A Study on Maternal Weight Gain and its Correlation with Birth Weight of Baby at Term

*S Rijvi¹, *S Abbasi², A Karmakar³, SF Siddiqui⁴, F Dewan⁵

ABSTRACT

Background: Maternal weight gain is influenced by several trends in perinatal health that are of great public health concern. Maternal weight gain during the 2nd and 3rd trimesters is an important determinant of fetal growth.

Objective: To determine the relationship between maternal weight gain and birth weight of baby at term.

Methodology: A cross sectional observational study was carried among 50 pregnant women at term were admitted in the Department of Obstetrics and Gynaecology, Shaheed Suhrawardy Medical College and Hospital and Anwer Khan Modern Medical College hospital during the period of January 2014 to July 2014. Data were collected pre-designed data collection sheet.

Results: This study found maximum (36%) were age group 21-25 years followed by 28% were ≤ 20 years, 24% were 26-30 years, 8% were 31-35 years and only 4% were 36-40 years. The average age was 25 years. Among these 50 pregnant women, 2 cases (4%) had BMI <18.5, 15 cases (30%) had a BMI 18.5-24.9, 19 cases (38%) had a BMI 25-29.9 and 14 cases (28%) had a BMI ≥ 30. The mean birth weight was 2.77±0.33 kg. Mean weight gain was 10.72±3.72 Kg. Weight increased there was a corresponding increase in the mean birth weight and this relationship was statistically significant (<0.05).

Conclusion: This study shows maternal weight gain significantly increased birth weight of the baby at term. Maternal weight should continue to be given importance in monitoring the health of pregnancies and bioelectrical impedance analysis and arm measurements should be further investigated as another simple way to track appropriate body composition changes across gestation, especially in resource-limited settings. Although challenging, public health efforts should continue working to improve the nutritional status of women of reproductive age before they conceive as an apparent way to improve birth outcomes.

Key Words: Maternal weight gain, Birth weight

Introduction

Birth weight is an important predictor for survival and health.¹ Infants with a low birth weight (less than 2,500 g or more than 4000 g) have increased perinatal morbidity and mortality as well as an increased risk of adulthood hypertension and type 2 diabetes.² For many years the focus has been on increasing birth weight, which is positively correlated with maternal weight gain during pregnancy. However, although a high maternal weight gain tend to decrease the incidence of low birth weight, an excessive weight gain may entail fetal as well as maternal complications, such as pregnancy and delivery complications and obesity later in life.³

AKMMC J 2018; 9(1) : 22-28
Prepregnancy body mass index (BMI) is an important predictor of birth weight. It is therefore important to combine maternal weight gain and prepregnancy BMI in analyses of the association between weight gain and infant birth weight. In the American Institute of Medicine (IOM) introduced weight gain recommendations for pregnant women with different recommendations for underweight (BMI less than 19.8 kg/m²), normal weight (19.8 - 26.0 kg/m²), overweight (26.1-29.0 kg/m²), and obese women (BMI more than 29.0 kg/m²).

Weight gain during pregnancy has been associated with high birth weight and measures of adiposity early in life. Because high birth weight predicts BMI later in life, these findings suggest that excessive weight gain during pregnancy could raise the long-term risk of obesity-related disease in offspring. High birth weight might also increase risk of other diseases later in life, including asthma, atopy, and cancer.

Low weight gain in pregnancy is associated with increased risk of preterm delivery, particularly if women are underweight or of average weight before pregnancy. But still there is increasing evidence that higher weight gains during pregnancy do not improve infant outcomes and instead may elevate the mothers’ long-term risk of chronic disease.

Sally et al. found that mean birth weight of infant increased by 20.2 g per kilogram of weight gain during pregnancy. In study conducted by Abrams and Selvin too, the mean birth weight of the infant increased by 22.6g/kg GWG. In the study by Nahar was 5.69 (SD= 1.95) kg.

Birth weight was correlated both with maternal weight in early pregnancy and with weight gain during pregnancy, but only 10% of the variation in birth weight was explained by these maternal factors. Mean maternal weight 24 h postpartum was equal to the weight at 14 weeks of pregnancy, implying, on the average, no net weight gain. Women with a positive net weight gain had heavier babies than women with a negative net weight gain.

Maternal anthropometric characteristics are important underlying determinants of intrauterine growth and birth weight, but they explain only a minor part of the variation and are of little value for screening purposes in individual women.

Maternal weight gain is one of the most important independent predictors of infant birth weight. Birth weight (BW) is an important determinant of infant’s well being. Several factors such as mothers’ genetic characteristics, socio-cultural, demographic, behavioural factors, prepregnancy body mass index (BMI), gestational weight gain (GWG) etc contribute to birth weight. BW is important as low birth weight is known to increase the risk of adult onset diseases like type-2 diabetes and ischemic heart disease.

Nevertheless, maternal weight gain is associated with large infants i.e., macrosomia (>4000 g) or large for gestational age infants who have higher risk of birth injuries and other problems like shoulder dystocia, fractures of the clavicles or limbs, and perinatal asphyxia. The total amount of weight gained in normal-term pregnancies varies considerably among women and the variance appears to be due to many maternal characteristics and pregnancy outcomes.

Weight gain during pregnancy has always been a matter of great concern for most women and obstetricians. This concern exists because gestational weight gain is related to many complications, both maternal and fetal. Macrosomia is a major fetal complication, consisting of cases of infants born weighing more than 4,000 g, regardless of the gestational age.

For mothers, the most common complications in macrosomic fetuses include: increased risk of intrauterine death, hypertrophic cardiomyopathy, need for intensive care, shoulder dystocia, humeral and clavicle fractures, meconium aspiration, hypoglycemia, neonatal hyperbilirubinemia, paralysis of the facial and brachial plexus and obesity in childhood and adulthood. For mothers, the most common complications include: increased risk of cesarean section, cephalopelvic disproportion, prolonged labor, soft-tissue lacerations and postpartum hemorrhage.

The present study was designed to determine the maternal weight gain and birth weight of baby at term. This study also help the planner of the hospital especially for resource allocation for weight gain of mother and birth weight babies at term.
Objective

To determine the relationship between maternal weight gain and birth weight of new born at term.

Materials and Methods

It was cross sectional observational study in department of Obstetrics and Gynaecology, Shaheed Suhrawardy Medical College and Hospital and Anwer Khan Modern Medical college hospital from January 2014 to July 2014. 50 Pregnant women were included in study. Inclusion criteria were all pregnant women at term who were in regular antenatal checkup (37 completed weeks of gestational age). Exclusion criteria were: The pregnant women suffering from Hypertension, Pre-eclampsia, Eclampsia, Diabetes mellitus, Thyroid dysfunction, Nephritis. Data were collected in pre-designed data collection sheet. A structured questionnaire was developed and pre-tester before administration by the author. Data was collected from the pregnant mother admitted in the in-patient department for a period of 6 months. The data were collected face to face interview for relevant information and measured the weight and height of the women before delivery and weight of the neonate were measured following delivery. Mother’s weight was measured by a valid & reliable weighing machine. Mother’s height was measured with a height measuring scale. A valid and reliable neonatal weighing machine determined the neonatal weight. Written informed consent was taken from each patient. Prior to consent they were explained the aim and purpose of the research. Confidentiality was assured and anonymity was maintained; no participants were identified in any report or publication under this study.

Results

Table-I: Age distribution of the patients (n=50)

<table>

</tr>
</tbody>
</table>

Table shows that 24% of the new born has birth weight ≤ 2.5 kg and 76% had birth weight > 2.5 Kg. The mean birth weight was 2.77±0.33
associated with an increased risk of small for gestational age (SGA) infants, especially in underweight and normal-weight women.\(^{14}\)

Birth weight is perhaps the most important and reliable indicator for neonatal and infant survival, its physical growth and mental development. As a universal indicator, it can be used to describe the health, nutrition and socio-economic status of population in both developed and developing countries. Currently, the incidence of low birth weight in India is 33 percent and as per National Health Policy efforts are being made to bring down the incidence to 10 percent by the year 2000 AD.\(^{15}\)

This study found maximum (36%) were age group 21-25 years followed by 28% were 20 years, 24% were 26-30 years, 8% were 31-35 years and only 4% were 36-40 years. The average age was 25 years. This findings consisted with Rao et al.\(^{16}\) study they found 25.2 years. Majority of the study subjects were housewives (88%), literate (60%), and belonged to middle income group (60%). This study found majority were housewife (88%).

Regarding educational status, 4% were illiterate, 36% were can sign only, 12% were primary education, 20% were secondary education, 20% were higher secondary and 8% were master degree. In monthly income, 4% were monthly upper income group (>10000/month), 60% were middle income group (>5000-10000/month) and 36% were lower income group (<5000/month). Height of the study subject, 8% had birth weight ≤45 Kg, 16% had birth weight 46-55 Kg, 40% had birth weight 56-65 Kg and 36% had birth weight >65 Kg. Among these 50 pregnant women, 2 cases (4%) had BMI <18.5, 15 cases (30%) had a BMI 18.5-24.9, 19 cases (38%) had a BMI 25-29.9 and 14 cases (28%) had a BMI ≥30. These women were categorized in BMI under weight, normal, overweight and obese. Yazdani et al.\(^{17}\) study shows Among these 1000 pregnant women; 128 cases (12.8%) had BMI <19.9, 412 cases (41.2%) had a BMI 20-24.9, 356 cases (35.6%) had a BMI 25-29.9, 98 cases (9.8%) had a BMI 30-34.9 and 6 cases (0.6%) had a BMI ≥35.

This study shows 24% of the new born has birth weight ≤2.5 kg and 76% had birth weight >2.5 Kg.

**Table-VI:** Relationship between maternal weight gain and birth weight of new born (n=50)

<table>
<thead>
<tr>
<th>Maternal weight gain (Kg)</th>
<th>Number</th>
<th>Birth weight</th>
<th>P value</th>
</tr>
</thead>
<tbody>
<tr>
<td>≤5 Kg</td>

</tr>
</tbody>
</table>

*Table shows that under weight mother had significantly lower birth weight and overweight and obese mother had significantly higher birth weight. This findings found statistically significant correlation between BMI and birth weight (P<0.05).*

**Discussion**

Maternal weight gain during pregnancy influenced by several trends in perinatal health that are of great public health concern. Women are increasingly gaining weight during pregnancy complications associated with excess gestational weight gain such as large-for-gestational-age babies. This is also important as the prevalence of Cesarean delivery has also increased. Maternal weight gain during the 2nd and 3rd trimesters is an important determinant of fetal growth. Low maternal weight gain is associated with an increased risk of small for gestational age (SGA) infants, especially in underweight and normal-weight women.\(^{14}\)

Birth weight is perhaps the most important and reliable indicator for neonatal and infant survival, its physical growth and mental development. As a universal indicator, it can be used to describe the health, nutrition and socio-economic status of population in both developed and developing countries. Currently, the incidence of low birth weight in India is 33 percent and as per National Health Policy efforts are being made to bring down the incidence to 10 percent by the year 2000 AD.\(^{15}\)

This study found maximum (36%) were age group 21-25 years followed by 28% were ≤20 years, 24% were 26-30 years, 8% were 31-35 years and only 4% were 36-40 years. The average age was 25 years. This findings consisted with Rao et al.\(^{16}\) study they found 25.2 years. Majority of the study subjects were housewives (88%), literate (60%), and belonged to middle income group (60%). This study found majority were housewife (88%). Regarding educational status, 4% were illiterate, 36% were can sign only, 12% were primary education, 20% were secondary education, 20% were higher secondary and 8% were master degree. In monthly income, 4% were monthly upper income group (>10000/month), 60% were middle income group (>5000-10000/month) and 36% were lower income group (<5000/month). Height of the study subject, 8% had birth weight ≤45 Kg, 16% had birth weight 46-55 Kg, 40% had birth weight 56-65 Kg and 36% had birth weight >65 Kg. Among these 50 pregnant women, 2 cases (4%) had BMI <18.5, 15 cases (30%) had a BMI 18.5-24.9, 19 cases (38%) had a BMI 25-29.9 and 14 cases (28%) had a BMI ≥30. These women were categorized in BMI under weight, normal, overweight and obese. Yazdani et al.\(^{17}\) study shows Among these 1000 pregnant women; 128 cases (12.8%) had BMI <19.9, 412 cases (41.2%) had a BMI 20-24.9, 356 cases (35.6%) had a BMI 25-29.9, 98 cases (9.8%) had a BMI 30-34.9 and 6 cases (0.6%) had a BMI ≥35.

This study shows 24% of the new born has birth weight ≤2.5 kg and 76% had birth weight >2.5 Kg.
The mean birth weight was 2.77±0.33 kg. The observed mean birth weight in the present study is comparable to studies conducted by Prasad et al.\textsuperscript{18} and Rodrigues et al.\textsuperscript{19} who observed a mean birth weight of 2823.6 gm (SD=417.8 gm) and 2815.0 gm (SD=449.3 gm) respectively. In this study shows among 4% of women, weight gain during pregnancy was ≤5 kg in 68% weight gain was 6-10 kg and 28% weight gain was >10 kg. The mean weight gain was 10.72±3.72 Kg. This findings consisted with Rao et al.\textsuperscript{20} study. The mean weight gain during pregnancy obtained in this study was also comparable to other studies carried out in India.\textsuperscript{21,22} However, the studies conducted by Barbara\textsuperscript{23} and Ekblad et al\textsuperscript{24} found mean weight gains during pregnancy of 15.4 kg (SD=5.2 kg) and 13.0 kg (SD=3.0 kg) respectively which were higher than the findings of the present study.

In this study, we observed that there was a significant correlation between maternal weight gain and fetal birth weight. It is indicated that with an increase in maternal weight gain during pregnancy there was a corresponding increase in mean birth weight and this increase was statistically significant (P<0.05). This findings consisted with Moreira et al.\textsuperscript{25} and they found significant correlation between maternal weight gain during pregnancy and birth weight of the new born. Another study Hymphreys\textsuperscript{26} reported maternal weight gain during gestation is positively correlated with birth weight. A population-based study conducted in the United States has shown that maternal weight gain during pregnancy correlates with birth weight.\textsuperscript{27} Rao et al.\textsuperscript{28} evaluated the relationship between various factors such as multiparity, pregestational overweight or obesity, advanced maternal age, prolonged gestational age and excessive gestational weight gain with the manifestation of fetal macrosomia. In that study, only excessive gestational weight gain was significantly associated with macrosomia.\textsuperscript{29} Many studies conducted in India\textsuperscript{30,31} and in different parts of the world\textsuperscript{32,33} have proved the positive relationship between weight gain during pregnancy and birth weight. This study found significant association of BMI during pregnancy and birth weight of the new born. It found BMI below normal associated with low birth weight and BMI >30 higher birth weight. The latter result is similar to other studies from Ushakiran\textsuperscript{44} and Bhattacharya.\textsuperscript{34} Yazdani et al. reported BMI below normal is associated with a low birth rate, while a BMI >30 increases the chance on a higher birth weight (2500-4000 or higher). This only suggests that weight gain during pregnancy is perhaps the most important variable irrespective of maternal height and period of gestation. It is a well established fact that period of gestation has an independent effect on birth weight.

Conclusion

Weight gain during pregnancy, and maternal weight have emerged as maternal factors influencing the birth weight of the baby. In the present study, it was found that there was a direct relationship between maternal weight gain and fetal birth weight. Although challenging but public health efforts should continue working to improve the nutritional status of women of reproductive age before they conceive as an apparent way to improve birth outcomes.
