Feeding adequacy among Critically Ill Patients in the Intensive Care Unit and Its Association with Clinical Outcomes: A Narrative Review

Zheng-Yii Lee¹, Mohd-Yusof Barakatun-Nisak², Ibrahim Noor Airini³*

Abstract

The Intensive Care Unit (ICU) is one of the disciplines in the hospital that provides close monitoring to the seriously ill or injured patients, also known as the critically ill patients. Critically ill patients in the ICU are usually unable to maintain volitional oral nutrition intake and therefore require nutritional therapy. Nutritional therapy can be delivered via the enteral or parenteral route. Optimal nutrition adequacy (i.e. neither underfeeding nor overfeeding) is very important for better clinical outcome. However, the problem of suboptimal feeding adequacy continues to be reported over the years. This article attempts to give an overview of the literature on feeding adequacy and the relationship of feeding adequacy with clinical outcomes among the critically ill patients in the ICU.

Keywords: Critical Illness, Intensive Care Unit, Nutritional therapy, Feeding Adequacy

Introduction

The Intensive Care Unit (ICU) is one of the disciplines in the hospital that provides close monitoring to the seriously ill or injured patients,¹ also known as the critically ill patients. Critically ill patients are often unconscious and may not be able to breathe adequately by themselves. Their respiratory function is often compromised and presents with low blood pressure, leading to poor oxygen perfusion to the vital organs.² Therefore, they are usually intubated and mechanically ventilated, given inotropes and vasopressors (drugs to support their blood pressure) and sedated. Their hemodynamic status is frequently unstable. Such conditions commonly predispose to multiorgan dysfunction as a complication, with a higher mortality rate seen in those with a higher number of organ failure.³

Critical illness is defined as “A life-threatening process…that ultimately involves respiratory, cardiovascular and neurological compromise”.⁴ Oral intake is almost always impossible in these patients,¹ necessitating the provision of artificial nutrition (i.e. feeding). Feeding the critically ill patients was previously regarded as adjunctive care (known as nutritional support). However, feeding is now regarded as nutritional therapy that may help to attenuate stress response, prevent oxidative cellular injury and favorably modulate immune responses.⁶

Figure-1: Enteral and Parenteral Nutrition

Enteral nutrition delivers nutrients into the gastrointestinal tract via a feeding tube. Depending on where the tube ends and how the tube is inserted into the gastrointestinal tract, enteral nutrition can be in the form of nasogastric tube, nasoduodenal tube, nasojejunal tube, gastrostomy tube and jejunostomy tube. Parenteral nutrition, also known as intravenous alimentation, delivers nutrients directly into the bloodstream. Total parenteral nutrition and peripheral parenteral nutrition delivers nutrients via the central and peripheral line, respectively.

Nutritional therapy can be delivered via the enteral or parenteral routes (Figure 1). Enteral nutrition (EN) delivers nutrients into the gastrointestinal tract via a feeding tube for patients who are unable to maintain volitional intake. Parenteral nutrition (PN) delivers nutrients directly into the bloodstream, via central or peripheral line. Compare to PN, EN has additional benefits of maintaining gut structural and functional integrity, modulating metabolic response, and attenuating oxidative stress and the inflammatory response while supporting the humoral immune system. Therefore, EN (i.e. tube feeding) acts as the first line nutritional therapy in mechanically ventilated critically ill patients who are unable to maintain volitional intake. While the rationale of initiating feeding to patients who are unable to maintain oral intake is justified, the effort to ensure patients are fed optimally based on nutrition prescription are often neglected. Studies have reported that critically ill patients receiving inadequate energy and protein are presented with poor clinical outcomes such as increased risk of infections, length of mechanical ventilations, morbidities and mortality. Although the definition of underfeeding differs in various studies, but it was generally recognized that 80% of prescribed energy and protein represent adequate feeding. It may be more important to ensure protein adequacy as studies have shown that improvement of clinical outcomes is associated with adequate protein intake, even after adjustment for energy adequacy. However, caution also need to be taken to avoid overfeeding patients, which is usually defined as feeding over 110% of energy prescribed, as it is associated with complications such as hyperglycemia, azotemia, hypertriglyceridemia, electrolyte imbalance, immunosuppression, alteration in hydration status, hepatic steatosis, and difficulty waning from mechanical ventilation.

Over the years, suboptimal feeding continues to be a major concern in the critically ill patient population despite various studies reporting on the relationship between nutritional adequacy and clinical outcomes. Factors associated with suboptimal feeding need to be investigated and action is needed to address this issue. This paper aims to review the literature that reported on feeding adequacy and studies that investigated on the relationship between feeding adequacy and clinical outcomes.

**Methods**

The literature search was conducted in electronic databases i.e. PubMed and Google Scholars up to December 2016, limited to articles published in English language. Studies included in this narrative review are adult (≥18 years old), critically ill patients who were admitted into the ICU, and nutritional therapy (EN or PN) initiated during the ICU stay.

For prevalence of underfeeding, studies must report energy and/or protein adequacy; while for studies reporting on the relationship between nutritional adequacy and clinical outcomes, at least one of the important clinical outcomes such as mortality, infectious complications, length of ICU and/or hospital stay or duration of mechanical ventilation must be reported. Studies in non-critically ill patients were excluded. In addition, studies that investigated on PN route and timing were also excluded.

**Results**

**Feeding Adequacy in the World, Asia & Malaysia**

Several single-center studies had reported the energy and/or protein adequacy among critically ill patients (Table 1). McClave et al showed that ICU patients (n=44) received about 51.6% of their targeted calorie requirement, while De Jonghe and colleagues found that 71% of calorie requirement was effectively delivered by both EN and PN route. On the other hand, Binnekade et al reported on average about 66% and 54% of energy and protein respectively was delivered among the 403 critically ill patients investigated.

On the global level, two international, prospective, observational study was conducted in year 2007 and 2008. In 2007, 158 ICUs from 20 countries with 2946 mechanically ventilated patients who stayed in ICU for at least 72 hours showed that average nutritional adequacy across sites was 59% (range, 20.5%-94.4%) for energy and 60.3% (range, 18.6%-152.5%) for protein. In year 2008, the second study involved 179 ICU from 18 countries with the same patient population (n=2956) showed that the average energy adequacy across sites was 56.2% (range, 20.3%-90.1%).

The most recent international multi-center observational study across 6 different geographic regions (Europe & South Africa, Canada, Australia & New Zealand, Latin America, Asia & USA) from 26 countries, 201 ICUs and 3390 patients showed that on average, patients receive 61.2% ± 29.4% and 57.6% ± 29.6% of prescribed energy and protein, respectively, with a mean energy balance of - 695 ± 532 kcal/day. When zoomed into Asia, a result lower than the international average was seen. On average, patients received 53.5% ± 28.0% and 51.9% ± 30.1% of prescribed energy and protein, respectively, with a mean energy balance of -736 ± 480 kcal/day. The prevalence of iatrogenic underfeeding (defined as received <80% of prescribed energy) was 74% at the international level, and 82% for Asia region.

In Malaysia, three single-center studies had been conducted to investigate feeding adequacy among critically ill patients. A small cross-sectional study in Hospital Selayang among critically ill patients on total enteral nutrition (n=67) presented by Mageswary et al showed that before appropriate feeding protocol was implemented, about 69.0% of patients achieved goal calorie (>70% of prescribed calorie) on day 5 after feeding initiation. Yap et al showed that 66% of patients achieved 80% of prescribed energy within 3 days of admission at Universiti Malaya Medical Center. Lee et al in their preliminary study in a Malaysian public hospital showed that the average energy and protein adequacy was 71.8% and 62.4%; while patients with high nutrition risk had lower adequacy, with average adequacy of 67.9% and 60.3% for energy and protein, respectively.

In summary, critically ill patients received approximately 50-70% of their energy and protein requirements.
Feeding adequacy and its implication to clinical outcomes

Inadequate feeding among critically ill patients is associated with poorer clinical outcomes such as increased infectious complication, length of ICU and hospital stay, duration of mechanical ventilation, and mortality, although such association was not consistently demonstrated in recent studies. The association between feeding adequacy and clinical outcomes are reviewed.

Small observational studies

About eight small observational studies (Table 2) among critically ill patients conducted in various countries demonstrated the association between underfeeding and poorer clinical outcome. In 2005, Villet et al. conducted a prospective observational study on 48 surgical patients who stayed in ICU for ≥5 days. It was shown that negative energy balance correlated with increase length of stay (p=0.0001), infections (p=0.0042) and length of mechanical ventilation (p=0.0002). Rubinson et al. studied 138 medical ICU patients who was nil by mouth for ≥96 hours and showed that after adjustment for potential confounders, patients who received ≥25% of recommended calories was associated with a significantly lower risk of bloodstream infection [relative hazard 0.27, 95% confidence interval (CI), 0.11-0.68]. Dvir et al. (2006) in a prospective study of 50 ICU patients also found that patients with negative energy balance of >4000 kcal has strong association with complications such as respiratory distress syndrome (p=0.0003), sepsis (p=0.0035) and renal failure (p=0.0001).

In a retrospective study of 295 patients, Tsai et al. demonstrated that patients receiving lower energy delivery was 2.43 times at risk of ICU mortality than high energy delivery.

ICU: Intensive Care Unit, ER: Energy requirement, PR: Protein requirement, d: day, h: hour, SAPS II: Simplified Acute Physiology Score II, APACHE II: Acute Physiology and Chronic Health Evaluation II, SOFA: Sequential Organ-failure Assessment, INS: International Nutrition Survey
delivery after adjusting for confounders (p=0.020). Furthermore, a study in 3 medical/surgical ICUs among mechanically ventilated patients who stayed in the ICU for more than 72 hours and received EN showed that successful EN may be associated with reduction in infectious complications, particularly after 96 hour of ICU admission.24 For protein, Albringstrup et al25 also found that increased protein provision was associated with significant decrease in hazard ratio of death, even after adjusted for baseline prognostic factors.

**Large Multicenter observational studies**

Large multicenter observational studies (Table 2) was conducted since the commencement of the International Nutrition Survey (INS) in year 2007. Since then, about 5 analyses were conducted based on the international sample. In year 2009, a large international observational study on 2772 mechanical ventilated patients by Alberda et al26 showed an increase of 1000 kcal and 30 g protein per day was associated with reduced 60-days mortality [odds ratio (OR) 0.76, 95% CI 0.61-0.95, p=0.014] and an increased in number of ventilator free days (VFD) (3.5 VFD, 95% CI 1.2-5.9, p=0.003). Elke et al27 selected a sample of 2270 ICU patients with sepsis and/or pneumonia from the database of the INS from year 2007 to 2011 also showed that an increase of 1000 kcal and 30 g protein per day was associated with reduced 60-day mortality (OR 0.61, 95% CI 0.48-0.77, p<0.001), and more ventilator-free days (2.81 days, 95% CI 0.53-5.08, p=0.02).

The relationship between nutritional adequacy and long-term outcome was also investigated. In a large sample (n=475) of patients who were mechanical ventilated for >8 days in ICU and had at least 2 organ failures related to their acute illness, survival time with low nutritional adequacy was significantly shorter than high nutritional adequacy (Hazard Ratio 1.7, 95% CI 1.1-2.6) and health-related quality of life was significantly higher with every 25% increase nutritional adequacy at 3 month follow up.28

On the contrary, Krishnan et al28 showed that lower adequacy was associated with better outcomes than higher levels of calorie intake. Arabi et al29 also showed that there was a dose-effect relationship between increasing calorie intake and higher hospital mortality, risk of ICU-acquired infections, rate of ventilator-associated pneumonia (VAP), increase duration of mechanical ventilation and length of stay in hospital and ICU. However, these associations were shown to be influenced by the statistical methodology used. Heyland et al30 found that analyses that do not account for the progression to oral intake and the number of ICU days used in the calculation of the proportion calories received will lead to a potentially erroneous finding whereby higher calories intake is associated with increased mortality, whereas analyses that account for these key factors showed that better fed patients have reduced mortality.

In fact, Heyland et al30 in the same study of an international sample of 7872 mechanically ventilated, critically ill patients who remained in the ICU for at least 96 hours showed that the overall association between percentage of the caloric prescription received and mortality is highly statistically significant with increasing calories associated with decreasing mortality (p<0.0001), and it appears that approximating goal of 80% of prescribed calories (and not more than 100% of prescribed calories) is associated with the best survival, regardless of body mass index. Similar results for protein was also demonstrated by Nicolet al31 among 2828 patients in ICU for at least 4 days, whereby patients who received ≥80% of prescribed protein had reduced mortality and shorter time-to-discharge alive, after adjusted for covariates and energy intake.

**Randomized controlled trial (RCT)**

Beside observational studies, several RCTs had been conducted in recent years (Table 3). Rice et al conducted the EDEN pilot (2011, n=200)31 and multicenter RCT (2012, n=1000)32 to investigate the effect of initial lower volume trophic or full enteral feeding for the first 6 days since ICU admission among patients with acute lung injury. Both studies achieved significant difference in calories and protein intake between the full and trophic feeding groups. The pilot study showed that the VFD to day-28, hospital mortality rate and ICU-free days were similar between groups. The multicenter RCT confirmed the results of the pilot study and showed no significant different between groups on VFD to day-28, 60-day mortality, development of infections and organ failure-free days.

The TICACOS study33 is currently the only RCT that uses indirect calorimetry to calculate energy requirement, shows that there is a trend towards reduction of hospital mortality (p=0.058) and significant lower organ failure score at day 3 (p=0.027) in the intervention group who received significantly more calories and protein than the control group. However, the control group had a significant lower length of mechanical ventilation (p=0.03), length of stay in ICU (p=0.04), and trend towards reduce VAP (p=0.08) and infectious complications (p=0.05). These contradicting results is most probably due to calorie overfeeding as the study investigators did not consider intravenous non-nutrition energy intake (such as dextrose-containing fluids and propofol), which corresponds to an additional 10-15% calories.34 Similar problem exists in a trial by Braunschweig et al35 which showed 5.67 times higher hospital mortality in the full feeding group. The possibility of overfeeding is noted in their figure 2 that from day 5 onwards patients consistently received ≥100% of their energy prescription and almost reaching 120% on day 13 and day 14, probably contributing to the high mortality of the full feeding group.

In year 2014, Peake et al36 randomized patients to receive isonitrogenous enteral formula with caloric density 1.5 kcal/ml and 1.0 kcal/ml. It was found that the 1.5 kcal/ml group who received significantly more calories had trend toward improved duration of survival (p=0.057), although there was no difference on VFD to day-28 and ICU & hospital length of stay. In the same year, Petros et al37 also found that patients who are fed more adequately had reduced nosocomial infection, despite no difference in mortality rate.

The intention-to-treat results were presented for Singer et al., 2011

MV: Mechanically-ventilated, ICU: Intensive Care Unit, LOS: Length of stay, d: day, VFD: ventilator-free day, SOFA: sequential organ failure assessment, VAP: ventilator-associated pneumonia. =: No significant difference, ↑: significantly increased, ↓: significantly reduced

Arabi et al\(^9\) in year 2011 found that the full feeding group in their study had higher hospital mortality, and trend towards longer ICU length of stay, duration of mechanical ventilation as well as higher 180-d mortality. However, it must be noted that the absolute caloric intake between group were small (~184 kcal/d) despite reaching statistical difference, and the protein intake of the underfeeding group was higher than the full feeding group. Therefore, it is hard to attribute the poorer clinical outcome in the full feeding group to greater nutritional intake. The same authors in year 2015 conducted the PERMIT multicenter trial\(^9\) which randomized patients to receive permissive underfeeding (40-60% of caloric requirement) or full-feeding (70-100% of caloric requirement) with similar protein intake. It was shown that there was no significant difference in all important clinical outcomes (mortality, length of stay, VAP) except that the permissive underfeeding group had a lower incident of renal replacement therapy (p=0.04).

In a nutshell, results from RCTs tend to show there is no significant difference in clinical outcomes between patients who received more calorie and/or protein, although some of them did show a trend towards better survival in patients who received more nutrition. Findings from RCTs combined with the signal of improved clinical outcomes in better fed patients shown in various multicenter prospective observational studies should allow us to conclude that optimal calories and protein provided to critically ill patients may improve patients’ outcomes, provided overfeeding is avoided. The use of nutritional screening tools such as the NUTRIC score\(^40\) in stratifying patients who require full or hypocaloric feeding is an important consideration but is out of the scope of this review.

**Recommendation and Conclusion**

The relationship between optimal feeding adequacy (neither underfeeding nor overfeeding) and better clinical outcomes (improved survival, reduced length of stay and infectious complications) is shown in many observational studies, while some RCTs showed reduced infections and mortality with better feeding adequacy. Despite this relationship, feeding adequacy was suboptimal, which warrants further investigation on the contributing factors so that a more informed action can be taken to address this issue.

In Malaysia, data regarding feeding adequacy and the factors associated with suboptimal feeding adequacy among the critically ill patients are still lacking. It is suggested that these factors are investigated in future research. This is because it is imperative to first discover the scope of the problem and factors associated with poor feeding practices, which then act as a ‘stepping stone’ for the implementation of effective solution to improve nutritional delivery and status, ultimately leading to better overall clinical outcome and cost-saving in the Malaysian ICU.
