In-hospital Outcome of Use of Low Molecular Weight Heparin in Patients Undergoing Percutaneous Coronary Intervention

Tariq Ahmed Chowdhury¹, Mustafizul Aziz², Iftekhar Alam³, Abuduz Zaher⁴, Sayed Azizul Haque⁵, Abdul Wadud Chowdhury⁶

Abstract:
This prospective observational study was carried out in the Department of Cardiology of national institute of cardiovascular diseases (NICVD), Dhaka to assess the safety of low molecular weight heparin (LMWH) in patients undergoing percutaneous coronary intervention (PCI).

Safety of low molecular weight heparin in comparison to unfractionated heparin (UFH) was observed in this study. In total data from 100 patients undergoing elective PCI was evaluated. Among them 50 patients in group I received 1 mg/kg intra-arterial LMWH and rest in group II received UFH.

Demographic profile of individuals in both groups was almost similar. There was no significant difference in major coronary risk factors between the two groups. Patients were monitored during their stay in hospital for any complications like bleeding, haematoma, myocardial infarction and death. No death was observed in any group. Minor bleeding in group I and II (6% vs 105), Major bleeding (2% vs4%) and haematoma (6% vs 10%). Myocardial infarction no incidence in group I and 4% in group II. So complications was more prevalent in group II who were treated with UFH, but those were not statistically significant.

The intra-arterial administration of LMWH in patients undergoing PCI is safe. The risk of acute and sub-acute coronary events and bleeding complications are similar in both groups and in hospital outcome there is less complication with LMWH used during PCI.

Key words: Percutaneous Coronary Intervention, Heparin, Low-Molecular-Weight.
and activation of thrombin. The important pharmacologic characteristics that distinguish LMWH from UFH include: greater bioavailability; minimal plasma protein and vessel wall binding; more predictable anticoagulant response; ease of subcutaneous and intravenous administration; and inhibition of acute phase release of von-Willebrand factor in acute coronary syndrome.

LMWH have earned their place and established their superiority over UFH in the management of post-surgical deep vein thrombosis and acute coronary syndrome (ACS) including unstable angina (UA) and non ST elevated myocardial infarction (NSTEMI). The efficacy and safety of subcutaneous Enoxaparin a LMWH used in NSTEMI showed enoxaparin plus aspirin was superior to UFH plus aspirin in patients with ACS. The need for urgent revascularization was significantly lower in enoxaparin group. LMWH represent a major advancement in the management of patients with ACS or as part of the strategy in candidates undergoing coronary interventions.

Several trials have shown that the LMWH enoxaparin offer the practical and potential pharmacologic advantages over UFH in multiple applications and logically should also provide a similar benefit during percutaneous coronary intervention (PCI). However, during coronary and non-coronary interventions, UFH is conventionally used more frequently than LMWH. Data from randomized, controlled clinical trials support the administration of LMWH and/or platelet GP IIb/IIIa inhibitor in patients who represent with non ST elevation ACS.

Small or noncomparative trials have evaluated a single intravenous bolus of enoxaparin in different doses form, such as: 1 mg, 0.75 mg or 0.5 mg per kilogram of body weight, in patients undergoing PCI with or without the administration of glycoprotein IIb/IIIa inhibitors. However, these uncontrolled studies have not allowed definite conclusions to be drawn about the efficacy of enoxaparin as compared with that of standard anticoagulation regimens involving unfractionated heparin. In a meta-analysis of data from randomized studies comparing intravenous low-molecular-weight heparins and intravenous unfractionated heparin in patients undergoing PCI, there was a nonsignificant trend toward a reduction in major bleeding with LMWHs and no difference between groups in the occurrence of ischemic events. In an additional analysis, a dose of less than 1 mg of enoxaparin per kilogram resulted in fewer ischemic and bleeding events than a dose of 1 mg per kilogram.

The use of LMWH eliminates the need for continuous intravenous infusion, anticoagulation monitoring and dose adjustment associated with UFH. Despite evidence-based support for administering LMWH and/or GP IIb/IIIa receptor blocker to patients undergoing PCI and those presenting with ACS, algorithms for integrating these agents into clinical practice have not been determined. The NICE trials have evaluated this issue in details and the results of these trials are likely to have a major impact on the choice of adjunctive therapy during PCI.

The ease of intravenous use, good & predictable anticoagulation response and absence of monitoring need make LMWH enoxaparin a very affective choice for heparinization during PCI. So this study is undertaken to assess the suitability and safety of intravenous LMWH to that of unfractionated heparin in patients undergoing elective PCI and to determine in hospital outcome regarding complications of UFH.

**Method:**

This prospective observational study was done in the department of cardiology of the national institute of Cardiovascular diseases (NICVD) during May 2004 to December 2004. Approval for the study was obtained from the institutional review board. All patients gave written informed consent. Patients undergoing percutaneous coronary intervention at NICVD were included in the study and depending on the type of heparin used patients were divided in two groups. In group I 50 patients were included who received intra-arterial LMWH e.g. Enoxaparine 1mg/kg during PCI. In group II 50 patients were included who received conventional UFH. Patients with Creatinine >2 mg/dl, Platelet count <100000 / mm³ and with Liver disease (INR> 1.3) were excluded from the study.

All patients initially evaluated by history, physical examination, 12 Lead ECG, CK-MB, and echocardiography. Pre catheterization investigations including CBC, Clotting time, bleeding time, HBsAg, VDRL, anti HCV, anti HIV was done as required. Diagnostic angiogram and PCI was done as standard method. Patients were randomly assigned to receive an intravenous bolus of unfractionated heparin, adjusted for activated clotting time according to current guidelines or intravenous enoxaparin at a dose of 1mg per kilogram. All patients received aspirin (300mg) and thienopyridines two hours prior to the procedure. Patients who were assigned to enoxaparin group received a single intravenous bolus of enoxaparin, without anticoagulation monitoring, after sheath insertion and immediately before PCI. When procedures were prolonged by more than 2 hours, an additional bolus of enoxaparin (half the original dose) was used. Patients who were randomly assigned to receive unfractionated heparin were given an initial intravenous bolus of 10,000 IU after crossing the lesion with
guide wire to achieve a target activated clotting time of 300 to 350 seconds. Unfractionated heparin was re-administered during the procedure when measurements of activated clotting time dropped below the recommended range. Activated clotting time was measured with a standardized Hemochron device (ITC). Sheath removal was done in UFH group at an activated clotting time between 150 and 180 seconds, 4 to 6 hours after the end of PCI. In group I who received 1 mg of enoxaparin per kilogram no monitoring of anticoagulation was required before sheath removal and sheath was removed within 2 to 4 hours after the procedure. Post PCI continuous monitoring done during the whole hospitalization period. Follow-up for ischemic complication, bleeding events, abrupt closure, vascular events and death was monitored. The occurrence of major or minor bleeding during the first 48 hours after the index PCI, according to pre-specified definitions. Major bleeding: Fatal bleeding. Retroperitoneal, intracranial, or intraocular bleeding. Bleeding that causes hemodynamic compromise requiring specific treatment. Bleeding that requires intervention or decompression of a closed space to stop or control the event. Clinically overt bleeding, requiring any transfusion of ≥1 unit of packed red cells or whole blood, causing a decrease in hemoglobin of ≥3 g/dl or a decrease in hematocrit of ≥10%.

Minor bleeding: Gross hematuria not associated with trauma. Epistaxis that is prolonged, repeated, or requires plugging or intervention. Gastrointestinal hemorrhage. Hemoptysis. Subconjunctival hemorrhage. Clinically overt bleeding, causing a decrease in hemoglobin of 2 to 3 g/dl. Hematoma >5 cm or leading to prolonged or new hospitalization. Death from any cause, nonfatal myocardial infarction (defined by a new Q wave in two or more leads or a total creatine kinase level or creatine kinase MB fraction that was ≥3 times the upper limit of the normal range during hospitalization for the index PCI or that was ≥2 times the upper limit of the normal range after discharge), or urgent target-vessel revascularization after the index PCI. Smoking was the most common risk factor among the groups. Incidence of other risk factors were similar in between the groups.

Among single vessel treated in group I, most common vessel was LAD 25(50%) followed by RCA 14(28%) & LCX 4(8%), and in group II, most common vessel was LAD 23(46%) followed by RCA 11(22%), LCX 6(12%) and LM 2(4%). Among the double vessel treated in group I, most common vessels were LAD & RCA 5(10%), LAD & LCX 1(2%) and RCA & LCX 1(2%) and in group II, most common vessels were LAD & RCA 5(10%), LAD & LCX 2(4%) and RCA & LCX 1(2%) (P value> 0.05).

In group I single stent was used in 38(76%) patients, double stents were used in 11(22%) and no stent was used in 1(2%) patients. However in group II single stent was used in 36(72%) patients, double stents were used in 12(24%) and triple stents were used in 2(4%) patients. There is no statistical difference between the groups (P value> 0.05).

The incidence of post PCI complications was more prevalent in group II then group I. there was no incidence of death during the study period among the groups.

None of the patients in group I suffered post PCI myocardial infarction but in group II 08 (16%) patients suffered from post PCI infarction. The prevalence of minor and major bleeding, haematoma was higher in group II compared to group I. There is no statistical dissimilarity between the groups (P value> 0.05).

Discussion:
This was a prospective observational study conducted in the department of cardiology, national Institute of Cardiovascular Disease, Dhaka. There was no published data in Bangladesh comparing effects of two types of heparin in PCI. Hence the result of this study was not possible to be compared with any other Bangladeshi studies but the results have shown similarity with studies done abroad.

Similar pattern of age distribution were reported by Jakub Drozd et.al. There was similar type of risk factor distribution like hypertension, smoking, dyslipidaemia, diabetes mellitus and Family history of CAD in both groups. Similar observation was found by Jakub Drozd et.al.17

Heparin has always been used during PCI and in spite of the progress which took place in interventional cardiology it still remains a standard treatment during and after this procedure. The goal of heparin treatment is to decrease the risk of acute restenosis of a vessel undergoing PCI and to prevent thrombo-embolic complications associated with introduction of instruments into the cardio-vascular system. The risk of acute restenosis may be as high as 11%. Acute reocclusion may be complicated by such severe events as death, MI or urgent need for redo PCI. The main limitations of heparin therapy are not fully predictable effects of this agent on the coagulation system due to variable binding to serum protein, platelets and endothelial cells. Therefore, the continuous monitoring of blood coagulation parameters is mandatory. At present, no generally accepted scheme of heparin administration prior to PCI exists. Usually a bolus of
10,000 iu of heparin is given, followed by serial ACT measurements every several minutes. This regimen has two limitations. First, the standard dose of heparin is not effective in some patients whereas in some others it is too high. Second, the costs of serial ACT measurements are not negligible. Ogilby et al. revealed that 11% of patients had ACT <300 seconds following 10,000 iu of heparin. Dougherty et al. have demonstrated a very wide range of ACT measurements every several minutes. This regimen has 250-275 seconds in 17%, ACT 275-300 seconds in 12% and >300 seconds in 13% of patients.

The ESSENCE studies have documented the advantages of enoxaparin over standard heparin in patients with acute coronary events resulting in lower risk of death, MI or the need for revascularization. Similar encouraging results were obtained by the TIMI IIIB investigations. The promising results of the above mentioned studies encourage the use of LMWH during PCI. Data in literature concerning this topic are very scant. The safety of enoxaparin administration (1 mg/kg) before PCI was examined in the open-label study. The rate of acute coronary complications was 4.9% whereas the rate of bleeding complications- 0.6%. The randomized study REDUCE compared 10,000 iu bolus of standard heparin with reviparin (LMWH) administered at a dose of 7,000 iu anti Xa. A significant reduction in the coronary event rates during the first three days following PCI was documented in the reviparin group (8.2% vs. 3.9%, respectively). Randomized patients to enoxaparin (1 mg/kg) or UFH 10,000 iu, given before PCI. The rate of coronary events, haemorrhage and local bleeding complications was similar in both analyzed groups, however, 30% of patients receiving UFH required additional doses of heparin to achieve the target ACT(>300 s). A study conducted in Poland revealed that in patients with acute coronary events enoxaparin given at a dose of 1mg/kg prior to PCI was equally safe as standard heparin titrated according to ACT.

Safety of enoxaparin in comparison to UFH observed in this study was evaluated in 100 patients. Among them, 50 received enoxaparin and similar number received UFH. Demographic profile of individuals in both groups was almost similar. There was no significant difference of major coronary risk factors between the two treatment groups. Patients were monitored up to hospitalized period for observation of any complications. No death was observed in any group. Major and minor complications was comparatively similar in both groups but relatively there was better outcome in LMWH group.

**Study Limitations**

Although the results of this study support the hypothesis there are some facts to be considered which might affect the results:

1. The study was a non-randomized and observational study.
2. Number of study population was limited.
3. Duration of follow up period was short.

**Conclusion:**

The intra-arterial administration of 1 mg/kg of enoxaparin in patients undergoing PCI is safe. The risk of acute and sub-acute coronary events and bleeding complications are similar in patients treated with UFH. The study was a non-randomized study with small number of patients. So further comparative study which will be randomized, with larger group will give a clear picture of clinical outcome between patients having enoxaparin and UFH in PCI.
