ABSTRACT

Papillary and follicular thyroid carcinomas, together known as differentiated thyroid carcinomas (DTC), are among the most curable of cancers. Distant metastases are rare events at the onset of DTC. Sites of metastases from follicular thyroid cancer (FTC) are usually osseous, and those from papillary thyroid cancer (PTC) metastasize to regional nodal basins and the lungs. Visceral metastases are rare, but the involvement of multiple sites has been reported so far. Liver metastases from differentiated thyroid carcinoma (LMDTC) are rare. We present the case of a patient with follicular variant of papillary thyroid carcinoma (FVPTC) unusually involving the liver.

Key words: Differentiated thyroid carcinoma, Solitary liver metastasis, Rare thyroid metastases.

Bangladesh J. Nucl. Med. Vol. 22 No. 2 July 2019

INTRODUCTION

Differentiated thyroid carcinoma (DTC), encircling follicular and papillary carcinomas, has good prognosis and long-term survival rates. In reality, 80–95% of the patients survive at least 10-years (1). DTC are relatively rare despite the common frequency of thyroid nodules (2). The prevalence of distant metastases at the time of the initial presentation of DTC is 4%. During the treatment period and follow-up, the prevalence of distant metastases ranges from 2% in low-risk patients to 33% in high-risk patients. Distant metastases occur primarily in the lungs than in the bones. The prognosis of distant metastases is usually bad with poor outcomes. Only 50% of patients endure ten years after a diagnosis of the metastatic DTC (3–5). The median age at diagnosis is 45–50 years, with two to four times more frequent in women than men (6). However, the prognosis of the patients at higher risk for recurrent disease or even death depends on the age at diagnosis, stage, capsular involvement, nodal involvement, size, and histological type. Liver metastasis from thyroid cancer is a very rare event with a reported frequency of less than 0.5% (7). Metastatic liver disease from both follicular and papillary thyroid cancer is always multiple or diffuse and is usually associated with other hematogenous metastases in the lungs, bones, and the brain (8–16). Survival ranges from 1 to 60 months after the diagnosis of LMDTC (1).

CASE REPORT

An otherwise healthy, 72 years old female presented with swellings of the right side and middle of neck 7 years back. Suddenly she noticed a swelling in the right hypochondriac region of the abdomen, which gradually increased in size within 1 year. The patient had no cardiac, pulmonary, or renal diseases. There was no history of hepatitis, tuberculosis, diabetes or exposure to radiation.

INVESTIGATIONS AND TREATMENT

A high-resolution ultrasound scan (HRUS) of the neck revealed a multinodular goiter with bilateral enlarged cervical lymph nodes. The biggest neck node in the right measured 2.5 X 1.2 cm and that of the left 1.7X0.6 cm. Fine needle aspiration cytology (FNAC) primarily diagnosed FVPTC, and after total thyroidectomy, it was histopathologically confirmed. The patient neglected her visit to Nuclear Medicine (NM) and received no radioactive iodine therapy (RAIT). After almost 7 years, she reported again. We performed HRUS of the neck and whole abdomen due to painful, hard, slowly growing swelling in the right hypochondriac region of her abdomen. HRUS of the neck revealed multiple enlarged lymph nodes in both sides of the neck which sizes are increased in size compared to the previous scan.

The whole abdomen ultrasound revealed a reasonably large (6.2 X 6.0 cm), irregular shaped, solid, echogenic mass lesion in the antero-inferior aspect occupying the segments V and VI of the right lobe of the liver.
Computed tomography (CT) of the abdomen showed a big, hypodense area (7 X 6 X 5cm) in the right lobe of the liver located in segments V & VI and provisionally diagnosed as a case of hepatocellular carcinoma (HCC).

Ultrasound-guided fine-needle aspiration (FNA) from liver SOL cytologically confirmed papillary thyroid cancer with metastases in the liver. The patient was referred to the National Institute of Nuclear Medicine & Allied Sciences (NINMAS) for radioactive iodine ablation therapy (RAIT) with a high level of pre-therapy serum thyroglobulin (Tg) level (> 300 ng/ml) and a high anti-Tg antibody level of 205 U/ml. Ablation therapy was done with administration of 150mCi $^{131}$I(5550 Mbq) at NINMAS with proper isolation and radiation safety measures. Post therapy whole-body scan (RxWBS) showed intense radio-iodine uptake in thyroid bed and right lobe of the liver suggesting iodine avidity of the solitary metastatic lesion in the liver. Post therapeutic routine follow-up will be done after 3 months. As the lesion was iodine avid, so our plan was to repeat RAIT preferably after surgical resection of the liver mass preferably if possible. But the patient was lost and proper follow up could not be done.

The outcome of the well-differentiated thyroid carcinoma (WDTC) usually has a good outcome, but patients presenting with distant metastatic disease have less favorable outcomes. For this reason, many risk stratification algorithms are considered to be of high risk (18–21). Although the higher possibility of poor outcomes, recent treatment strategy advocates an aggressive approach in management with surgery and postoperative RAIT (20-23). Treatment consists of total thyroidectomy, neck dissection as indicated by the disease, followed by RAIT in the majority of patients. Distant metastases occur in up to 10% of the brain, eye, breast, liver, kidney, muscle, skin area are unusual (24). LMDTC from DTC is relatively rare, with a reported frequency of 0.5% (7). Metastatic liver involvement from DTC is nearly always multiple or diffuse and is usually found along with other distant metastases (lung, bone, and brain) (8-16).

Only ten cases have been documented in the literature; three were males and seven were females, with an average age of about 63 years (range: 32-85 years). Histologically, the primary tumor was identified as papillary in four patients, follicular in five patients, and Hurthle cell thyroid cancer in one patient.

Liver masses can be detected by various imaging modalities, such as ultrasonography and CT, and are usually131I negative. 131I-positive metastases are extremely rare. DTC liver metastasis has a poor prognosis. Surgical resection of liver lesions has been reported to offer the best chance for prolonged survival (24).

Most liver metastases from DTC are asymptomatic and usually revealed incidentally. This reported female patient had no definite complaint except swelling of the neck. HRUS proved multinodular goiter and bilateral enlarged cervical lymph nodes only could convince her for total thyroidectomy but neither follow up nor RAIT for histologically proven FVPTC was her choice and negligence. As an unfortunate sequel, she presented with a liver mass 7 years later which was cytologically proven as a solitary liver metastatic lesion from papillary thyroid cancer and high serum Tg( > 300 ng/ml). Even after explaining the benefits of surgical resection followed by RAIT as there is chance of prolonged survival (25), the patient refused metastatectomy of liver in this case and opted for RAIT with 150mCi 131 I . Unusual intense liver uptake of 131I in RxWBS was also a rare phenomenon in this case.

Kondo et al. (15) reported a case of a 48-year-old Japanese woman who was operated (subtotal thyroidectomy) for follicular adenoma of her thyroid. Eight years after the initial surgery, an isolated liver lesion was incidentally detected on abdominal CT. On histological examination, the nodule was entirely composed of...
small to large follicles containing colloid material. Thus she was diagnosed to have had minimally invasive follicular carcinoma with secondary isolated liver metastasis. The symptoms of the patient of our case had much similarities with their findings.

Kouso et al. (26) reported a case of follicular thyroid carcinoma in a 73-year-old woman who had undergone curative resection of thyroid carcinoma 32 years earlier. CT of her abdomen revealed a round lesion, approximately 1.5 cm in diameter. She underwent laparotomy and partial resection of her liver. Histological diagnosis was a metastatic liver cancer from thyroid follicular carcinoma.

CONCLUSION

The 131I WBS, role combined with HRUS and CT scan, plays an important role in increasing diagnostic accuracy, reducing pitfalls, and modifying therapeutic strategies.
