Nutrition of rice as influenced by reclamation techniques for acid sulfate soil in Cox’s Bazar

Md. H. R. Khan

Department of Soil, Water and Environment, University of Dhaka, Dhaka 1000, Bangladesh

Abstract

A field experiment was conducted for the reclamation of a Cheringa hot spot of acid sulfate soil manipulated by flash leaching followed by basic slag (BS; BS30; BS20: basic slag at 10 and 20 t ha-1), aggregate size (A; A20 and A30: aggregate sizes of soil less than 20 and 20-30 mm) treatments under two different techniques (Tech 1: pyrite layer at top, jarosite layer at middle and top soil at the bottom of ridge; Tech 2: top soil at top, pyrite layer at middle and jarosite layer at the bottom of ridge). Nutritional responses to two cultivars of rice with the treatments were evaluated. The initial soil had very low pH (H2O: 3.4), and high EC; 1.6 mS-1, and pyrite content, 76 g kg-1. Magnesium content (5.38 c mol kg-1) of the soil was about 3 fold than that of Ca (1.71 c mol kg-1), and Al content (9.22 c mol kg-1) was at a highly toxic level. The average soil data of all the treatments, except for the control plots after harvesting of rice were increased by 1.5 units for soil pH and 12 to 463% for the contents of N, P, Ca and Mg, while the concentrations of Fe, Al, Na, Cl and SO4 decreased by 27 to 93% compared with the initial soil.

The highest N, P, K, Ca, and Mg contents in both the BR 14 and Pizam rice shoots at maturity were obtained by the A20BS30 treatment. The other treatments also resulted in a significant (p≤0.05) improved performance on plant nutrition compared with the control. The local Pizam exhibited the best responses under the Tech 2 in order of these nutrient uptakes. Sulfur content in the rice plants on control plots was high (1.8-2.1 g kg-1) but it decreased significantly by the different treatments.

Keywords: Acid sulfate soil; Aggregate size; Basic slag; Nutrition of rice plant; Pyrite and Jarosite layers

Introduction

The availability of land for growing crops is limited; it may become inevitable to utilize marginal/problem soils and extend acreage under crop production to feed the hungry people. Among the problems, acid sulfate soils (ASSs) have been lasting severe environmental degradation, which affect some 100 M ha of land world-wide of which about 0.7 M ha are located in inundated coastal areas in Bangladesh where crop production is very low; some where the lands are unproductive though the soils have high agricultural potential (Van Mensvoort and Dent, 1998; Khan, 2000). The ASSs generate H2SO4 that brings their pH from 6-7 to below 4, and sometimes to as low as 2. This acid leaks into drainage and floodwaters, corrodes steel and concrete, and attacks clay liberating elements in toxic concentrations (Khan et al., 2002).

Conventional reclamation of ASSs through liming and flash-leaching is not sustainable (Khan et al., 1994) because soil acidity produced by 1% oxidizable sulfur requires about 30 t of CaCO3 ha-1 (Van Breemen, 1993). Usually ASSs contain 1-5% oxidizable sulfur and the use of more than 10 t lime ha-1 showed an antagonistic effect on micronutrient levels as well as on the balance of basic cations in plants (Khan et al., 1996). Neutralization of ASSs with lime and/or leaching leads to the deterioration of the soils, related ecosystems, and to permanent soil acidification (Khan and Adachi, 1999). Dent (1986) reported that basic slag from steel industry was effective in reducing soil acidity and also economical if available locally. Khan et al., (1994, 2006) reported that the application of BS in ASSs significantly increased soil pH, Ca and Mg with an associated decrease in Na, S, Fe and Al concentrations over time. Basic slag as a byproduct from the steel industry in Bangladesh can be collected almost free of charge. This BS had a very high pH of 9.6 and contained 20.8% Ca, 9.8% Mg, and 12.8% SiO2 (Khan et al., 2006). The previous techniques of plain-ridge-ditch or raised beds used for the reclamation of ASSs in Vietnam, Thailand, Indonesia and the Netherlands (Dost and van Breemen, 1982; Dent, 1986; Dent and Mensvoort, 1993), where pyritic materials were taken from the sub-soils, were covered by non-pyritic top-soils and followed by flash-leaching by rain or irrigation. These
techniques have not had much success and were not sustainable, which might be due to the lack of (i) proper oxidation of pyritic materials, (ii) neutralization of acidity, (iii) recovery of basic cations lost during leaching, (iv) mitigation measures against environmental threats arising from the acidity and toxic elements laden during reclamation. But in the present modified-plain-ridge-ditch-techniques, where different sizes of aggregates were used for proper oxidation of pyritic materials and BS for the neutralization (slit was used for in-situ neutralization to a deeper depth) as well as recovery of the basic cations lost during leaching; placement of pyritic materials in different patterns was considered on the basis of tidal influences and economic conditions of farmers. These integrated systems will not only reclaim the ASSs but will also safeguard the associated environment from the threats of acid drainage wastes.

Successful reclamation of the ASSs may result in the development of productive fields for crop growth. While poor soil reclamation may lead to the creation of unfavorable soil conditions for crop growth and formation of actual ASSs, the real problem is in the coastal tidal flat plain areas (Khan et al., 2007). Against this background, the objective of the present field study was to evaluate the nutrition of rice as influenced by basic slag, aggregate size treatments under Modified-Plain-Ridge-Ditch Techniques for the reclamation of acid sulfate soil.

Materials and methods

Experimental site and condition

A field experiment was conducted in a fallow land at Cheringa hot spot of ASS in the coastal old mangrove floodplain area in the Cox’s Bazar district of Bangladesh. The lands are usually inundated by saline seawater tides of about 0.2 to 0.6 m high (about 180 times a year). On the basis of tidal conditions, the height of the ridges constructed on plain land under the techniques used was 0.6 m. But during the experiment, the study site was protected from natural tides by a dike (1.5 m high) around the experimental site. The site enjoy ‘tropical monsoon climate’, has three main seasons, namely, the monsoon or rainy season, the dry or winter season and the pre-monsoon or summer season. This area in Bangladesh was once occupied for centuries by dense mangrove forest. Now about 95% of the areas have been cleared for agricultural cultivation. As a result, the potential ASSs have become actual ASSs with very poor yields or somewhere unproductive. Eight series of such ASSs were studied in the field on the basis of land type, land use, hydrological conditions and depths of acid forming layers. Among these, the Cheringa ASS at Sarisabari (Fig. 1) was selected for further studies in relation to the nutrition of rice.

Experimental design and field preparation

The experiment was set up in a completely randomized block design with three replications. There was an approximately 1.5 m wide and 1.0 m deep drain around the experimental field, about a 0.5 and 0.3 m boundary around each main plot and subplot, respectively for protecting the individual plot from the contamination of the treatments. The field of about 0.75 ha was divided into 12 main plots each having 10 x 5 m² sizes. In each main plot of plain or ridge, there were 6 subplots of 1 x 1 m² but there was no subplot in the ditch, which was about 10 x 5 m² wide and 0.4 to 0.6 m deep. The subplots of 1 x 1 m² were then used for individual treatment. These plots were irrigated mainly by using rainwater (yearly rainfall >4000 mm) collected from the local rain-fed channels through the irrigation pump. Pond water was also used for irrigation during the dry period. Saline water intrusion and drainage water were controlled through dikes and flap gates. Basic slag was collected from a steel industry and then grounded to less than 1 mm sizes in order to apply in the field. The rates of BS and BS (basic slag at 10 and 20 t ha⁻¹) were incorporated into the topsoil (depth: 0-0.2 m) by broadcasting during ploughing. For in-situ neutralization of acidity arising from jarosite and pyrite layers in the modified-plain-ridge-ditch techniques (Fig. 2), the same doses of BS were incorporated into the subsoil (0.2-0.4 m) by using a soil slitter (5 cm diameter) at every 0.2 m of distance.

Modified-Plain-Ridge-Ditch Techniques

Plain: The area of each plain plot (flood plain land) was 10 x 5 m² and the particle size of the soil in the plain plot was grounded manually into two aggregate sizes of about less than 20, and 20 to 30 mm (A and A). The grounded soils were then processed under the sun and open air for maximum oxidation within 2 days. The plain land was considered to reclaim by the application of flash-leaching (5-7 times of washing within a week: till the pH becomes >4.5 and lower ECe values) followed by the application of BS treatments (BS and BS as suggested by Khan, 2002). The drainage waters from the plain plots under the Modified-Plain-Ridge-Ditch techniques were disposed to the nearby ditches where the water was treated by BS as required to raise the water pH to 5.5.

Ridge: The ridge means a raised bed of about 0.6 m soil, stacked upon flood plain soil (plain land), which was made by raising different layers of soil through excavation and arranged as shown in the Fig. 2 (Tech 1 and Tech 2). These 0.6 m high beds were constructed to facilitate leaching of acidity and salinity from the soil. The area of the top of each ridge was similar to that of the plain plot. Particle sizes of the bed materials were grounded manually into two aggregate sizes of A and A (aggregate sizes of soil less than 20 and

2- and Cl⁻.

Technique 1: The top layer (surface soil) was extended to

about a 0.2 m thick layer (1st layer: 0-0.2 m) primarily onto

the adjacent plots and was grounded into different aggregate

sizes (A_w and A_w) as per treatment requirement and was kept

open to air for oxidation within 2 days. Then, the second

layer (0.2-0.4 m layer: sub surface soil with jarosite material)

was extended to about a 0.2 m thick layer onto that processed

first layer. The soil of the second layer was also grounded to

the desired sizes of aggregates and kept for oxidation within

2 days. Finally, the third layer (0.4-0.6 m layer: deeper soil

20-30 mm). These smaller sizes of aggregates were

considered in order to understand the effects of oxidation of

sulfidic materials (pyrite/jarosite) and their quick drainage

from this heavy-textured ASS. Each plot on the ridge of the

different techniques was brought into flash-leaching followed

by the application of BS treatments as practiced for the plain

plot. The drainage water into the nearby ditches was treated by

BS to raise the water pH till 5.5. The arrangements of soil

layers in different techniques were as follows:

Fig. 1. Site map of the study area (oval shape marked) in Cox’s Bazar of Bangladesh.
containing pyrite material) was placed at the top of the previously stacked layers. This third layer was also considered for the preparation of different sizes of aggregates and for the oxidation of 2 days. After that, the prepared 0.6 m raised beds were taken under extensive leaching (5-7 times washing within a week) with rain and pond water. Therefore, the top soil of the ridge was subjected to the different rates of BS application as per treatments designed for the experiment.

Technique 2: The preparation and processing of land such as aggregate size, duration of oxidation through air drying and experimental treatments were similar to those stated for Tech 1, except for the arrangement of soil layers. In Tech 2, within the ridge (raised bed of 0.6 m), the arrangement of soil layers was like the jarosite layer was placed at the bottom (3rd layer: 0.4-0.6 m), then the pyrite layer in the middle (2nd layer: 0.2-0.4 m) followed by the surface soil onto the top (0-0.2 m) of the ridge.

Ditch: Adjacent to each ridge, there was a ditch of about 10 x 5 m² having a depth of about 0.4 to 0.6 m attributed to the excavation of soil for the preparation of ridges. These ditches were constructed as a reservoir of acid drainage waters, where these acidic waters were neutralized by the use of BS during dry season. But during rainy season, these acidic wastes were automatically diluted by rain and/or controlled runoff waters.

Two aman varieties of rice (high yielding variety – HYV BR 14 and local Pizam) were planted in the Cheringa ASS. The top soil (0-0.2 m) in each plot (plain and ridge) was fertilized with N, P and K at the rates of 100, 80 and 60 kg ha⁻¹ as urea, triple super phosphate (TSP) and muriate of potash (MP), respectively as a basal dose. All the TSP and MP and one-third urea were applied just one day prior to transplantation whereas the rest of the two-thirds of urea were applied as top dressing two times after 30 and 60 days of transplantation. The plots were allowed to receive natural rain and pond waters whenever necessary to maintain favorable conditions (maximum saturated to field moist condition) for rice. Thirty day-old healthy and uniform seedlings were transplanted at the rate of four plants per hill. The distances between the hills were 15 cm. Pests were controlled by the use of the insecticide, ‘Nogos’ whenever it was required.

Soil analysis: The bulk samples obtained from the soil were stored for a couple of days under field-moist conditions (by putting the soil samples into polyethylene bags in an air-tight box) just prior to laboratory analysis, when the sub-samples were air-dried and crushed to 2 mm before analyses. After treatment with 1M CH₃COONH₄ (pH 5.0) and with 30% H₂O₂ to remove free salts and organic matter, respectively, particle size distribution was determined by the pipette method (Day, 1965). Soil pH was measured for the oven dried soil in soil-water (1:2.5) suspension using a Corning pH meter Model-7 as described by Jackson (1973). For saturation extract of soil, the electrical conductivity (Richards, 1954), water soluble Na⁺ and K⁺ (flame photometry: Black, 1965), water soluble SO₄²⁻ and Cl⁻ contents (Jackson, 1973); Ca²⁺, Mg²⁺, Fe³⁺ and Al³⁺ (atomic absorption spectrometry - AAS: Hesse, 1971) were determined. Organic matter content was determined (Nelson and Sommers, 1982) by wet combustion with K₂Cr₂O₇. Available N (1.5M KCl extraction; Jackson, 1973), available P (0.02N H₂SO₄, pH 3 extraction, Olsen et al. 1954) were determined. Cation exchange capacity was determined by saturation with 1M CH₃COONH₄ (pH 7.0), ethanol washing, NH₄⁺ displacement with acidified 10% NaCl, and subsequent analysis by steam distillation (Kjeldhal method: Chapman, 1965). Exchangeable Na⁺, K⁺, Ca²⁺ and Mg²⁺ were extracted with 1M CH₃COONH₄ (pH 7.0) and determined by flame photometry (Na⁺, K⁺) and AAS. Exchangeable Al³⁺ (1M KCl; Thomas, 1982) and Fe³⁺ (1M CH₃COONH₄; pH 4.8; Black, 1965) were determined by AAS.

Plant analysis: The composite samples of shoot dry matter at maturity were analyzed for N content by the micro-Kjeldahl method (Jackson, 1973); P content by spectrometry (Jackson, 1973); K content by flame photometry (Black, 1965); S content by turbidometry (Jackson, 1973); Ca and Mg contents by AAS (Hesse, 1971) in HNO₃-HClO₄ acid (2:1) digest. The level of significance of the different treatments was determined using Duncan’s New Multiple Range Test (DMRT) and least significant difference (LSD: Zaman et al., 1982).

Results and discussion

Pre- and post harvested soils

The studied Cheringa ASS (depth: 0-0.2 m) showed a silty clay loam texture, initially low pH of 3.4, pyrite content of 76 g kg⁻¹, low base saturation (34%), high ECe (1.6 S m⁻¹), high exchangeable Fe³⁺ and Al³⁺ contents of 1.83 and 7.91 cmol kg⁻¹, respectively (Table I). The contents of basic cations in the initial soil were low to medium, while acidic cations were very high in relation to the amounts found elsewhere. The pH value of the average soil data of all the treatments at post harvesting of rice was found to be increased in pH from 3.4 to 4.9, i.e. by 1.5 units higher compared with the control (i.e. initial value), while the ECe value of the soil was decreased to 0.38 S m⁻¹ (76% decreased over control: Table I). The contents of N, P, Ca and Mg in the average soil data at post harvesting were found to be increased (IOC = increased over control, i.e. initial value) by 12 to 463% IOC. The contents of exchangeable Al³⁺, Fe³⁺, Na⁺, Cl⁻ and SO₄²⁻ in the soil were

A₀²₀ and A₀₃₀ = Aggregate size less than 20 and 20-30 mm; BS₂₀ and BS₃₀ = Basic slag application at the rates of 20 and 30 t ha⁻¹. †In a column and row, means followed by a common letter are not significantly different at 5% level.
The post harvested soil data (Fig. 3) of pH, exchangeable K⁺, Ca²⁺, Mg²⁺, Fe³⁺ and Al³⁺ contents were found to be affected significantly (p≤0.05) by the application of basic slag and aggregate size treatments in different techniques. The application of A₁₀₀BS₁₀ attain the highest value of soil pH of 5.6 in the ridges of Tech 1 and 5.8 in the ridges of Tech 2 during post harvest followed by the A₅₀BS₅₀ (pH 5.2 in the ridges of Tech 1 and 5.3 in the ridges of Tech 2: Fig. 3) treatment. The lowest soil pH of 3.4 was recorded by the control treatment (where there was no exercise of A, BS and techniques). The contents of exchangeable Al³⁺ and Fe³⁺ during post harvesting were found to decrease sharply by the treatments and the decrements were more pronounced in the soil of the ridges of the techniques (Fig. 3). The highest amount of exchangeable Al³⁺ of 7.91 c mol kg⁻¹ was recorded for the control plots, while this value was decreased to 0.18 for Tech 1 and 0.11 for Tech 2 by the A₁₀₀BS₁₀ Preceded by the A₅₀BS₅₀ and A₁₀₀BS₊₀ treatments. The decrement was more pronounced with the Tech 2. Among the treatments, the application of BS ranked first followed by the aggregate size treatments and techniques for the increments of soil pH and nutrient status of the soil which might be due to basic nature of BS (pH 9.6) as well as its release of some elements mainly Ca, Mg, etc. into the soils. The results are agreed well with the findings of some researchers. Of them, Khan (2002) reported that the acid sulfate soils released a very large amount of Al, e.g. 10 mM L⁻¹. But a very low concentration of Al can be hazardous. Concentrations of 1 to 2 mM Al L⁻¹
are toxic to most crops and about 2 mM Al L$^{-1}$ is toxic for rice. Fishes are most susceptible, fish kills occur at 0.5 mM Al L$^{-1}$. Standards and potable water mostly range from 5 to 1450 µg Al L$^{-1}$ ($2 \times 10^{-4}$ to $6 \times 10^{-2}$ mol Al m$^{-3}$; Sittig, 1994). Khan et al. (2006) reported that the application of BS in ASSs significantly increased soil pH, Ca and Mg with an associated decrease in Na, Fe and Al concentrations over time. However, it was reported that the increase in pH by the application of slag fertilizer caused the decrease in Eh (Ponnamperruma et al., 1967; Nozoe et al., 1999). But the studied site is in a coastal belt, which receives daily tides (0.2 to 0.6 m high) more than 180 times a year. Therefore, the chance of decrease in Eh and its associated problems might be less for this study area.

Mineral nutrition of rice

*Nitrogen, phosphorus, and potassium*

The local Pizam exhibited the best responses on N, P, and K contents in rice shoot at maturity under the Tech 2. As
expected, the lowest contents of these nutrients in both the rice plants were recorded in the control treatment (Table II). The highest N, P, and K contents in both the BR 14 and Pizam rice plants were mostly obtained in the A20BS30 followed by A20BS30BS20 treatments under Tech 1 and Tech 2 (Table II). These increments were more pronounced with the rice grown on the ridges of both the techniques. The application of basic slag and aggregate size treatments in different techniques significantly \((p<0.05)\) increased the contents of these nutrients in rice shoot presumably due to reduced soil acidity and salinity as well as the release of N, P, etc. by microbial decomposition and associated soil chemistry with the treatments. Nitrogen \((r=0.94***, 0.97***\) for BR 14 and 0.95**, 0.96**\) for Pizam in Tech 1 and Tech 2, respectively), phosphorus \((r=0.86**, 0.97**\) for BR 14 and 0.94**, 0.96**\) for Pizam), and potassium \((r=0.94**, 0.99**\) BR 14; 0.95**, 0.96** Pizam) contents in both the rice shoot at maturity showed significant positive relationships with the grain yields of these rice cultivars.

**Calcium, magnesium and sulfur**

The Ca and Mg contents in the rice shoots increased significantly by the application of basic slag and aggregate size treatments in different techniques that created a favorable environment for the uptakes of the nutrients by the rice plants. The lowest contents of Ca and Mg in both the rice plant tissues were recorded in the control treatment (Table II). Sulfur content during maturity of both the rice plants grown in the control plots was high \((2.0-2.3 \text{ g kg}^{-1})\) and above the critical S content \((0.6 \text{ g kg}^{-1});\) Yoshida and Chaudhry, 1979). However, the S content in the rice shoots significantly \((p<0.01)\) decreased by the application of basic slag and aggregate size treatments in different techniques. The A20BS30 treatment was recorded for the maximum decrement of the S content in both rice cultivars grown on the soil of the ridges under both the techniques (Table II). The S content in both the rice shoots showed a significant \((p<0.01)\) negative relationship, while Ca and Mg contents showed a significant \((p<0.01)\) positive relationship with the grain yields of both the rice grown under the different techniques. The S content in the rice shoot was high due to the high concentration of sulfate (Table I) in the growing media and did not show a positive relationship in grain production.

**Conclusion**

It is concluded that the application of BS30, ranked first, followed by the A100 > A30 for the reclamation and improvement of the acid sulfate soil. The significant \((p<0.05)\) positive improvements on the nutrition of rice and soil properties were more pronounced under Tech 2 than those of Tech 1 under the modified-plain-ridge-ditch system. Application of basic slag and aggregate size treatments in different techniques not only increased soil pH, but also improved the ionic balance between Ca and Mg, and remarkably decreased the Fe and Al contents in the soil and plants.

The application of basic slag in the ASS was an effective measure and was also available at a reasonable price, which not only enabled reclaiming the soil and but also improved the nutrition of rice to optimum level. Moreover, the modified-plain-ridge-ditch techniques and the use of different sizes of aggregates contributed for the physico-chemical amendments of the soil as well as improved the ionic balance among the nutrition of rice. The local variety (Pizam rice) showed better response on the nutrition of rice than that of the high yielding BR 14 rice cultivar grown in the soil. However, for a cost benefit analysis of these treatments in relation to acid neutralizing capacity in different fields for a long time, further studies on different soils and crops under variable climatic conditions should be carried out.

**Acknowledgement**

The present research work was carried out by the financial and technical support of the Volkswagen and the Alexander von Humboldt foundations, respectively. The researchers and co-workers of the project are also gratefully acknowledged.
