Abstract

Background: Oral pyogenic granuloma is a soft-tissue lesion of the oral mucosa. This lesion has a tendency to recur after surgical excision. Materials and Methods: A total of 35 patients underwent surgical excision of pyogenic granuloma in the period from January 2019 to June 2022. Two surgical techniques were used to remove pyogenic granuloma: simple excision with root planing and modified excision with deep curettage. Results: Females (54%) were slightly more predominant than males (46%). The upper and lower jaws were almost equally affected by the lesion with more predilection toward the posterior region. The size of the lesion ranged from 0.5 to 3 cm in diameter with slow-growing rate. Rural residents were more affected (57%) than urban people. The lesion appears clinically as a small red mass with sessile base, and these clinical features were similar in pregnant and nonpregnant women. The recurrence rate was 14.8% and seen only in patients treated by simple excision. Histopathological feature was consistent with inflammatory hyperplastic lesion, and there was no radiographic evidence of bone resorption associated with the lesion. Conclusion: Modified excision with deep curettage prevents the recurrence of the lesion after 1-year follow-up.

Keywords: Clinical features, etiology, pyogenic granuloma, recurrence, surgery

Introduction: Pyogenic granuloma, which is a nonneoplastic soft-tissue lesion, occurs as a result of inflammatory reaction.¹ It is mostly affecting the gingiva and very rarely other sites of the oral cavity such as lip, tongue, and buccal mucosa.² Pyogenic granuloma is not considered as an appropriate term, as it does not occur as a consequence of granulomatous inflammation and does not contain pus material.³ Previous studies suggested that soft-tissue injury due to infection was the main cause of this lesion.⁴ Others, however, stated that the invasive stimuli of low-grade intensity behind the development of pyogenic granuloma.⁵ These include chronic irritation from dental calculus or retained roots and trauma. In addition, hormonal changes during pregnancy or puberty, and certain drugs such as cyclosporine could be the etiological factors of pyogenic granuloma.⁶ Besides, certain cases of pyogenic granuloma have been reported in patients who underwent guided tissue regeneration⁷ and dental implant.⁷

Pyogenic granuloma is usually seen in young adult females and most commonly occurring at the anterior gingiva of the upper jaw.⁸ Clinically, this lesion presented as exophytic mass with smooth or ulcerative surface. Though, sometimes the lesion appears as a small erythematous papule on a pedunculated or sessile base.⁹ The growing of pyogenic granuloma is slow and takes weeks to months to reach optimal size.¹⁰ Therefore, the size of the lesion during presentation ranges from few millimeters to 4 cm in diameter. Although there are many treatment modalities of pyogenic granuloma, surgical excision is still the treatment of choice to eradicate this lesion.⁶-¹⁰

Many researches showed that there was no recurrence following such a treatment modality. However, the recurrence of the lesion was reported and rated between 5.8% and 16% after surgery. The aim of this work is to study the clinicopathological aspect of pyogenic granuloma and to detect the recurrence rate after 1-year follow-up of two surgical techniques used to manage this lesion.

MATERIALS AND METHODS
Successive patients who underwent surgical excision of pyogenic granuloma in the department of Oral & Maxillofacial Surgery, Rajshahi Medical College Hospital, during the period from January 2019 to June 2022 were studied. A consent form was taken from each patient before surgical procedure. Patients' information (age, sex, and resident) and features of the lesion (site – anterior or posterior/upper or lower jaw, size and duration of the lesion, clinical feature, and recurrence) were reported and analyzed. The etiology of the lesion whether local factors such as bad oral hygiene and occlusal trauma or systemic factors like hormonal changes as in case of puberty and pregnancy were recorded as well. A periapical view was taken for all patients to detect bone resorption.

The lesion was excised under local anesthesia for all patients. To detect the effect of surgical technique on recurrence rate of the lesion, patients were divided equally into two groups: in the first group, the excision was confined to the original lesion followed by root planing of the adjacent tooth and removal of the local causative factors, and in the second group, 2 mm of the normal adjacent tissue was excised with deep curettage until healthy bone and removal of the causative agents. For brevity, the first technique was described as simple excision with root planing and the second technique was modified excision with deep curettage. The excised specimens were kept in formaldehyde solution and sent for histopathological investigation. Patients were instructed to improve oral hygiene using toothbrushing and flossing. Chlorhexidine mouthwash were prescribed for 1 week. The treated cases were followed up for 1 year to detect any possibility of recurrence. This study was approved by the Ethical Committee of Rajshahi Medical College Hospital.

Results
A total of 35 patients with pyogenic granuloma were studied, in which 16 (45%) were male, and 19 (55%) were female. The ratio of male to female was 1:1.18. Six cases out of 19 were pregnant women. The mean age of the affected patients was 35.7(±12.5), with an age range of 20–70 years. The most frequent cases of pyogenic granuloma were seen in the age group of 30–39 years, as shown in Figure 1.

Rural residents were more affected than urban people (57% and 43%). The upper and lower jaws were almost equally affected by the lesion, and the premolar–molar area of the upper and lower jaws was more predominant (36% and 64%) than the anterior part, as depicted in Table 1. Most of the cases presented clinically as a sessile lesion (72%). The size of the lesion ranged from 0.5 to 3 cm in diameter with duration ranging between 1 month and 10 months. The majority of the cases were developed as a result of bad oral hygiene (78%) and the rest due to hormonal changes during pregnancy, as shown in Table 2. After 1-year follow-up, four cases were reported with recurrence in the group treated by simple excision and root planing, whereas no cases of recurrence had been reported in patients treated by modified excision with deep curettage.

The high-level estrogen and progesterone during puberty and pregnancy deteriorate the already established gingival inflammation by increasing dilatation and proliferation of blood vessels and releasing vasoactive mediators from the damaged mast cells. It is thought that the expression of angiogenic factors such as basic fibroblast growth factor and vascular endothelial growth factor can be enhanced by trauma and female sex hormones which cause the development of pyogenic granuloma. In the present work, six cases were pregnant women, and the surgical excision was carried out in the second trimester. This is to avoid the side effect of surgery on pregnancy.

Both the jaws were almost equally affected by pyogenic granuloma, and the premolar–molar region was more predominant than the anterior one, particularly the labiobuccal aspect of the marginal gingiva. This is because the posterior portion is more subjected to occlusal trauma and difficult to clean during toothbrushing. These findings are in agreement with previous study.

Clinically, most cases of pyogenic granuloma presented as painless red mass tends to bleed easily upon probation and a smooth surface attached at a sessile base. A similar feature was seen by Jafarzadeh et al. but disagrees with that observed by Al-Khateeb and Ababneh where the lesion was ulcerated and a part of the lesion had pedunculated base. Pyogenic granuloma of short duration tends to bleed easily because of high vascularity and less collagen fibers, while mature lesion contains more collagen and less vasculature.

The role of oral hygiene and socioeconomic status (according to patient’s income) of the patients in the evolution of pyogenic granuloma was obvious in the present study, as more rural residents suffered from this lesion compared to that of urban people. However, the sample size in the present work may be not enough to judge about the distribution of the lesion between rural and urban population.

The size of the lesion in this research ranged between 0.5 and 3 cm in diameter and small lesion developed within 5–20 days, whereas larger one took longer time (6–9 months). This indicates that the development of pyogenic granuloma is slow, and this phenomenon was reported by other studies.

There are two techniques were used to manage pyogenic granuloma in this study. In the first group, simple excision (confined to the base of the lesion) was used followed by root planing of the adjacent normal tissue with deep curettage up to healthy bone and removal of the irritants was performed. This is to detect the effect of surgical technique on recurrence rate of the lesion.

Follow-up of the treated patients indicated that there was no evidence of recurrence in patients treated by modified excision with deep curettage. In contrast, the recurrence of the lesion was seen in 4 (14.3%) who treated by simple excision with root planing. The recurrence appeared with different intervals ranging between 10 months and 1 year. Although there were no huge differences between the two groups, this
indicates that removal of 2 mm from the normal tissue and deep curettage may have an influence in the prevention of recurrence of the lesion. It has been postulated that recurrence is ascribed to incomplete removal of the lesion and persistent of the causative agents. Therefore, 2 mm of the adjacent normal tissue was excised to ensure complete removal of the lesion.

Histopathologic examination of the excised lesion revealed pieces of rich vascular granulation tissue infiltrated with macrophages and other inflammatory cells consistent with that of pyogenic granuloma. In accordance with the study of Kamal et al., this study reveals that there was no radiographical evidence of bone resorption associated with the lesion.

Conclusion
Females in the fourth decade of life and rural residents were more prone to develop pyogenic granuloma. The posterior region of the upper and lower jaws, particularly labiobuccal aspect, was more affected by such a lesion. There is no difference in the clinical feature of pyogenic granuloma between pregnant and nonpregnant women. The majority of the cases occurred as a result of local factors such as deep pocket or retained roots. The size of the lesion was not exceeding 3 cm with slow-growing rate. Modified excision with deep curettage was successful to eradicate pyogenic granuloma with no recurrence after 1-year follow-up. Histopathologic investigation of the excised lesion was consistent with hyperplastic inflammatory lesion. Radiographically, there was no evidence of bone resorption associated with the lesion.
