INTRODUCTION:
Hand Foot and Mouth Disease (HFMD) is a contagious disease of children usually under five years of age characterized by sores in mouth and rashes over hands and feet caused by viruses. Most patients have mild symptoms, including fever and ...
rashes and herpes in the hands, feet, and mouth. A few cases may present with meningitis, encephalitis, pulmonary oedema, and circulatory disorders and even die of the diseases.\(^2\) Infection occurs through direct contact or droplets, via respiratory secretions such as saliva, sputum, and nasal discharge, contact with blister fluid of infected individuals and from other excretory materials of an infected person.\(^3\) The disease is primarily caused by Coxsackievirus A164 followed by enterovirus 71, though other strains of coxsackievirus and enterovirus may also cause the disease.\(^5\) There are reports of outbreaks in HFMD over the past several years in the tropical and subtropical regions of the world and the situation may worsen in future due to climate change and poor health care surveillance.\(^6\)

Seasonal variability in incidence of HFMD is noted in Japan\(^7\), Singapore\(^8\), Malaysia\(^9\), Taiwan\(^10\) and China\(^11\). Outbreaks of this disease in China, Singapore, Malaysia and Taiwan usually peak in the late spring/early summer, along with a second small peak in late autumn/early winter. In Japan\(^12\) its peak is detected during the summer months. However, in Finland most HFMD cases were reported in autumn.\(^13\) Peak of HFMD incidence in children in China was from May to July which might relate to the survival ability of enteroviruses.\(^14\) In Vietnam HFMD increased by 7% for 1°C increase in monthly temperature above 26°C & 1% increase in monthly humidity above 76%.\(^15\) In the same study, HFMD decreased by 3.1% with 1 mm increase in monthly cumulative rainfalls.

Though a study done in northern Bangladesh\(^16\) showed May and September-October as peak season for HFMD but meteorological variables affecting incidence of HFMD is not known in Dhaka, Bangladesh. This study was done to see the impact of meteorological factors like temperature, rainfall & humidity on the incidence of HFMD in Dhaka city.

**METHODS:**

**Topographical feature of the study area:**

The climate of Bangladesh is subtropical in the center-north and tropical in the south, with a pleasantly warm and sunny winter from November to February, a short hot spring between March and May, and a long rainy season from June to October due to the summer monsoon. The study was conducted in the capital city, Dhaka, which is located in central Bangladesh at 23°42′N 90°22′E, on the eastern banks of the Buriganga River.

**Meteorological condition of the study area:**

Dhaka experiences a hot, wet and humid tropical climate. Under the Köppen climate classification, Dhaka has a tropical wet and dry climate. The city has a distinct monsoonal season, with an annual average temperature of 25°C (77°F) and monthly means varying between 18°C (64°F) in January and 29°C (84°F) in August. Approximately 87% of the annual average rainfall of 2,123 millimetres (83.6 inches) occurs between May and October. The wettest month for Dhaka is July with an average of 367.9 mm of precipitation falling while the driest month is December with 8.9 mm falling.\(^17\)
Data collection:
The data of HFMD cases were collected from the Out-patient Department of Dhaka Shisu Hospital, a Tertiary Pediatric Hospital in Dhaka City over a period of 2 years from January 2018 to December 2019. According to the study protocol (based on WHO recommendations)\textsuperscript{18} a child was diagnosed as having HFMD who had a history of brief febrile illness accompanied by a typical skin rash with or without mouth ulcers. Once identified, a patient was treated either at the OPD setting or was admitted In-patient, depending on the severity of the condition. Total number of HFMD cases were recorded monthly during the study period from 2018 to 2019. Meteorological data were provided by Bangladesh Meteorological Department, under Ministry of Defense of the Government of Bangladesh, which among others, included monthly average temperature (°C), relative humidity (%) and amount of rainfall (mm). While the outcome variable was the monthly number of HFMD cases, the predictive variables were average temperature, humidity and rainfall during the study period. Data were analyzed using SPSS (Statistical Package for Social Sciences), version 25.0. The test statistics used to analyze the data were descriptive statistics. The qualitative data were expressed in frequency and corresponding percentage and the quantitative data were presented as mean and standard deviation from the mean.

RESULT:
Age distribution of the selected study children shows that nearly 30% of the patients were < 1 year old, 56.3% 1 – 5 years old and 14.7% 5 or > 5 years old with median age of the patients being 1.5 ± 0.2 years. Approximately 60% of the children were male with male to female ratio being 3:2 (Table I). From Table II & III and Fig. 5, it appears that there are clustering of HFMD cases between June to October (rainy season) when monthly average temperature, total rainfall and humidity all were peak compared to those in November to April (dry season) of the year. The clustering of cases was more intense in the year 2019 than that in the year 2018 as is evidenced from the graph of the time distribution of the HFMD cases. During the period average monthly temperature was 29.2°C, average rainfall was 62.6% of the total annual precipitation and mean relative humidity was 78.6%. The proportion of HFMD cases out of total cases treated during the period was 2.2% in 2018 and was 4.1% in 2019, which in the dry season (November to April) was 0.4% and 0.5% in 2018 and 2019 respectively.
DISCUSSION:

The present study is, by far, the first study examining the relationship between climatic variables and HFMD occurrence in Bangladesh. In this study majority (85.3%) of children was < 5 years old with a male predominance (60%) which is quite consistent with the findings of a large-scale South Korean study (which incorporated 7 years data from 2011 to 2017), where HFMD primarily occurred in children younger than 4 years of age with greatest proportion of cases being found at ages 1 (39.2%) and 2 (25.7%). Our study demonstrated a seasonal pattern of HFMD occurrence with a higher number of cases occurring in the monsoon season and a few cases in dry season. A recent study conducted in Vietnam showed that the number of HFMD cases increased during the rainy season and the number is determined by meteorological variables. An increased risk of HFMD was associated...
with higher average temperature (risk ratio and 95% confidence interval: 1.06; 1.03–1.08 per 1 °C increase), higher rainfall (1.19; 1.14–1.24 per 200 mm increase) and longer sunshine duration (1.14; 1.07–1.22 per 60 hours increase), while the risk of HFMD was inversely associated with wind speed (0.77; 0.73–0.81 per 1 m/s increase). A previous study in Vietnam also reported consistent result. However, the transmission rate of HFMD in three provinces of China explains the complex transmission dynamics. Meteorological factors cannot solely explain the seasonality in HFMD transmission in mainland China; the Chinese Spring Festival period, population flux and (or) school terms explain the majority of the transmission rate seasonality of HFMD, and they act as driving forces for HFMD transmission rate seasonality in different time periods of the year. The Chinese Spring Festival period dominantly caused the dramatic increase of the HFMD transmission rate during February due to population flux and seasonal contact rate in population. Some other studies in China also did not support the association between rainfall and HFMD. However, the South Korean study clearly showed that incidence of HFMD tended to increase from May, peak between July and September, and increase rapidly in 1- to 2-year cycles.

HFMD has seasonality. In temperate regions, the number of patients who are infected with enteroviruses rises in summer. In subtropical and tropical regions, enteroviruses circulate throughout the year and elevate during the rainy season. Pham and associates found each 200 mm increase in rainfall to be associated with a 19% increased risk of HFMD onset. A possible explanation is that high rainfall makes soil moist, which may facilitate viral persistence and spreading. Although, exact reasons for the relationship between climatic variables and HFMD are limited, meteorological factors like warm and moist weather could affect occurrences of infectious disease via survival and transmission of pathogens in the environment. Besides, population activities and behavior changes in different seasons may cause children vulnerable to acquire the infection.

Pathophysiology of enteroviruses was found to be affected by temperature, humidity and surface of fomites. Studies from Hong Kong Special Administrative Region SAR (China) and Japan revealed similar findings: a positive association between average temperature and number of HFMD cases. High temperatures could increase the growth of enteroviruses and also interfere with its inactivation. In agreement with some previous studies that humidity is associated with HFMD, the current study also observed an increasing trend of HFMD cases in the monsoon season when average relative humidity remains at its highest (79%).

Some studies included another climatic variable ‘sunshine hours’ and showed that HFMD cases increased with the increase of sunshine hours. Pham showed that the risk of HFMD increased by 14% per 60 hours of increase in sunshine duration. However, another study showed a negative correlation between sunshine duration and HFMD infection. As the present study did not included this variable, we cannot make any comment on the effect of this variable on the incidence of HFMD in different seasons of the year. Before concluding the findings of the study, the following limitations deserve mention.

Limitations:

1. HFMD epidemics have been shown to occur in two- to three-year cycles, and the two-year period in our study does seem to be adequate to identify the cycle of enteroviruses and the effects of climate change on HFMD. It would be useful to conduct a longer study and conduct time series analysis to detect the natural cycle of HFMD outbreaks in this region.

2. Besides, recorded database might be underestimated. There may be other pediatricians in the same hospital who might have treated HFMD cases but had not been recorded.

3. In addition, HFMD patients with mild self-limiting or unclear symptoms might not have been diagnosed as HFMD cases.

CONCLUSION:

The study concluded that majority of the HFMD cases occur under five years of age and boys are more
prone to acquire the infection than the girls. A seasonal pattern of HFMD occurrence is evident with a higher number of cases occurring in the monsoon season and a few cases in dry season. Clustering of HFMD cases occur between June to October when monthly average temperature, total rainfall and humidity all are at their peak compared to those in the dry season of the year. A large-scale, multicenter study, with inclusion of other meteorological variables and human behavioral factors, is recommended to study seasonality and transmission dynamics of HFMD in Bangladesh.
