Journal of Bangladesh Academy of Sciences, Vol. 34, No. 1, 59-70, 2010

ENERGY INTENSITY AND PRODUCTIVITY IN RELATION TO AGRICULTURE – BANGLADESH PERSPECTIVE

SHAIKH KHOSRUZZAMAN¹, M. ALI ASGAR², K. M. REZAUR RAHMAN³ AND SHAWKAT AKBAR³

Institute of Natural Sciences, National University, Gazipur-1704, Bangladesh

ABSTRACT

Results of the energy intensity and overall energetic efficiency show that total energy output increased from 69.87 to 82.08 GJha⁻¹, with increasing commercial energy input from 17.94 to 27.10 GJha⁻¹ during 1990 to 2005. The corresponding increase in energy intensity was 45.67 to 54.47 MJ/US\$(2000). Energetic efficiency, calculated as the ratio of total output to input for different crops, using weight factor, decreased from 3.97 to 3.03. The energetic efficiency declines with increasing energy input, and the result indicates that input energy increases faster compared to energy output. The mechanization index increased from 64 to 78%. However, the main goal being maximization of the output per unit agricultural land, the estimated change in efficiency with increasing input can play an important role in choosing the appropriate input for optimum output.

Key words: Energy intensity, Productivity, Agriculture

INTRODUCTION

The economic activity of Bangladesh is heavily dependent on agriculture in respect of employment, where 48% of the human labor is involved. This particular sector contributes only 12.929 billion US\$ (2000), which is about 21% of total GDP of 2008. This discrepancy in respect of output per person engaged in agriculture is mainly due to the backwardness in energy use in this sector considering the total energy use, its form and efficiency.

Energy intensity is a measure of efficiency of a nation's economy. It is usually calculated as unit of energy needed to produce per unit of GDP. The energy intensity in agriculture sector is calculated in three ways. In the first case, we considered the combined contribution of all sub-sectors of agriculture such as crops and horticulture, fishery, livestock and forestry taking into account only the commercial energy used such as petroleum, electricity. In the second case, only the crops and horticulture sub-sectors have been considered. In the third case only the crops and horticulture sub-sectors, taking into account all kinds of energy such as muscle power, mechanical power, chemical and bio-fertilizer energy and all other forms of final commercial energy used in irrigation have been considered.

The efficiency of agricultural practices can be computed in more than one way. Most people have calculated the efficiency of agricultural processes by converting the agricultural product into energy as output, and only the commercial energy in the form of energy from human, animal, machinery fuel, fertilizer, pesticide, irrigation fuel in the form of petroleum and electricity and energy from seed, and that again for a particular crop like rice and wheat (Alam et al. 2005), boro rice (Iqbal 2007) and sugarcane (Mrini et al. 2001). We have calculated the efficiency of agricultural process as practiced in Bangladesh by taking into account the total agricultural product in the form of different kinds of crops such as rice, wheat, maize, jute, oil seed, pulses, vegetable, potato, sugarcane, spices, cotton and groundnut, and their residues, which have been converted into energy as output. The input energy is considered in two ways. Firstly, by considering only the commercial input, and secondly by taking the total energy input, which includes solar energy and the commercial energy. The first approach is important when the aim of the agriculturist is rather narrow and commercially to find out how much agricultural output one receives out of the agricultural investment, without taking into consideration the net output of the cultivated land. In the second approach which we have called the total energy efficiency, the aim is to find out the efficiency of converting solar energy by agriculture as increased through the additional input of commercial energy in the form of energy from human, animal, machinery, fertilizer, manure, pesticide, irrigation fuel (petroleum and electricity), as also from water and seed. We have also calculated the change in these two efficiencies from 1990 to 2005 on the basis of the agricultural practices in Bangladesh.

Many researchers have studied energy intensity and energy efficiency, Schaeffer, *et al.* (2005), reported that in Brazil the agriculture energy intensity was 3 MJ/US\$-2000 ppp in 1980. Mrini *et al.* (2001), determined the energy efficiency of sugarcane in Morocco. Canakci *et al.* (2005), determined the energy efficiency of citrus, apricot, tomato, cotton, sugar beet, greenhouse vegetable, some field crops and vegetable in Turkey. Previously many researchers have calculated efficiency with respect to different types of crops (Alam *et al.* 2005) where the inclusion of commercial input is not exhaustive. In fact, with the progress of time, the nature of the commercial input is changing due to modernization of agriculture and the introduction of new devices. We have considered a more exhaustive list of inputs as practiced in Bangladesh in recent time.

The main consideration in this paper has been the goal of maximizing agricultural production from our limited cultivated land. Despite of various shortcomings of the land utilization system, Bangladesh has greatly increased its food grains from 31 million MT to 42 million MT during 1990 to 2005, and achieved self-sufficiency in food production in 2000. It is also found that machinery fuel energy, fertilizer energy, pesticide energy and irrigation (petroleum and electricity) energy consumption in agriculture sector have greatly increased in recent years, and the output of the agriculture also increased though

the cultivable land decreased slowly which was 9.78 million hectare in 1990 and has been reduced to 7.32 million hectare in 2005. Under this situation, an energy scenario in agriculture can provide planners and policy makers an opportunity to evaluate the performance of agriculture system in respect to energy input.

In this study, we evaluate the role of energy in GDP and energy intensity, the role of energy in energetic efficiency and the role of energy in agricultural production as food that is energy productivity.

MATERIALS AND METHODS

The available up-to-date data from different national and international published sources have been used here. In those cases, where no published data are available, the relevant figures from field survey have been estimated. Human and animal labor, machinery, electricity, petroleum and fertilizer have been included to estimate the energy intensity. The energy equivalents of these different forms of energy used for the computation have been estimated (Khosruzzaman et al. 2009). The energy supply by human labor has been calculated accordingly (Iqbal 2007). To estimate the gross energy input in agriculture, working day of agricultural worker is considered as 207 days per year, with an average 8 hr work per day (Stout 1990). The average working hours of an animal in agriculture is considered 360 hr per year (Ozkan et al. 2004). Since, there is no data available for petroleum (diesel) consumption of the machinery used in agriculture, the total diesel energy input to agriculture was calculated from the petroleum consumed by tractors and power tillers. From field investigations, it is found that a 70-hp tractor consumes 8 L diesels per hour and its average use on the field is 1140 hr per year. On the other hand, a 10-hp power tiller consumes 1.75 L diesel per hour with an 80% loading capacity and its average use on the field is 720 hr per year (Ozkan et al. 2004). Deep tube-well, shallow tube-well and low lift pump are operated by electricity and diesel. Data on electricity and diesel, used in irrigation were collected from field investigation. It is found that for irrigation, a deep tube-well consumes 1388 KWh electricity per hectare, shallow tube-well and low lift pump consume 266.4 L diesels per hector. Chemical energy input data on individual fertilizer materials (nitrogen, phosphorus, potash and zinc); manure and pesticides (insecticide, herbicide and fungicide) were used on the basis of practices (Ozkan et al. 2004). The total energy input from fertilizer was calculated from the chemical energy released by the different element of the fertilizer usage (Khosruzzaman et al. 2009). The energy contributions from the pesticide were also calculated. The energy contribution from water was estimated by considering the total water needed for irrigation and the energy released per unit quantity of water (Khosruzzaman et al. 2009). To calculate water energy, used in irrigation, it is assumed that 1.33 kg of water is consumed to produce 1 gm of wheat and 0.45 kg of water is consumed to produce 1 gm of rice and other food grains. This amount of water, was also converted to energy equivalent (Acaroglu 2005). Seed is considered as a form of energy input to agriculture. In this study rice, wheat, maize, jute, oil seed, pulses, vegetable, potato, sugarcane, spices, cotton, groundnut and their residues were considered as output in the energy estimation. Energy output from these products was calculated by multiplying the amount of production and their corresponding energy equivalent. Energy output from the by-products was estimated by multiplying a by-product with its corresponding energy equivalent (Khosruzzaman *et al.* 2009).

Based on the energy equivalents of the inputs and output (Khosruzzaman *et al.* 2009), the energy input to produce per unit of GDP output (energy intensity), the energy ratio (energetic efficiency), energy productivity and the mechanization index have been evaluated of the period 1990 to 2005 as defined below (Sartori 2005).

Energy intensity
$$= \frac{\text{Energy input (MJ/ha)}}{\text{GDP US}\$(2000)}$$
(1)

Energetic efficiency =
$$\frac{\text{Energy output (MJ/ha)}}{\text{Energy input (MJ/ha)}}$$
 (2)

Energy productivity =
$$\frac{\text{Grain output (kg/ha)}}{\text{Energy input (MJ/ha)}}$$
 (3)

Mechanization index =
$$\frac{\text{Commercial energy input (MJ/ha)} \times 100\%}{\text{Energy input (MJ/ha)}}$$
(4)

NUMERICAL ANALYSIS AND DISCUSSIONS

Energy intensity reflects the economic return of energy. High-energy intensity indicates a high cost of converting energy into GDP, while lower energy intensity indicates higher GDP per unit energy use. The energy intensity reflects the standard of living and the state of the economy.

Energy intensity: The relationship between energy intensity and economic development has the following pattern - in the initial stage, where agriculture is more conventional, human and animal muscle power plays significant role, energy intensity is lower since the productivity is also low. In the second stage that is the initial phase of the modernization of agriculture, energy intensity increases because of increased energy investment to develop the infrastructure, application of chemical fertilizer, the introduction of new machineries and techniques and also in the preparation of manpower and acquisition of specialized knowledge. In the third stage, energy intensity decreases due to increased efficiency of agricultural productivity through modern technology and efficient utilization of various forms of energy. In Bangladesh we have not been able to go through this third phase transition in either agriculture or industry yet. In the following sections, the sectoral energy intensity is discussed.

Energy intensity in agriculture sector: Agriculture is the single largest sector in the economy of Bangladesh. The combined contribution of all sub-sectors of agriculture such

as crops and horticulture, fishery, livestock and forestry in GDP was about 21% in the year 2008 and 48% of the total labor force was employed in this sector, (Table 1). However, in 1990, this sector shared high growth rate of about 10%, of which, crop subsector contribute about 80% of the GDP and about 57% of the labor force was engaged in this sub-sector.

	1990	1995	2000	2005	
Active human labor (million)	50.15	54.59	39	47.4	
Human labor in agriculture sector (million)	33.3 (66%)	34.5 (63%)	20 (51%)	22.8 (48%)

Table 1. Agricultural statistics of Bangladesh (BBS 1992-2008, LFS 1995-2006, LS 1998-1999).

Over the last 15 years it is found that although there had been expansion of irrigation accompanied by increase of crop production, due to the absence of planned irrigation management, it had adverse impact on environment in some areas of the country. For example, sub-soil water level fall and water became unavailable for long-term irrigation. In addition, until the mid of 1980s, traditional irrigation system with inefficient equipment had been used. The historical energy intensity from 1990 to 2008 and projected intensity for the period 2009 to 2035 for the historical GDP growth and energy

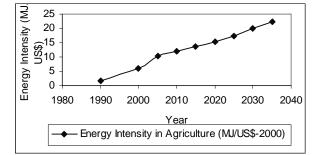

Fig. 1a. Projected energy intensity scenario in integrated agriculture sector of Bangladesh with commercial energy used.

of the agriculture sector of the country is shown in Fig. 1a. It is realized that the energy intensity slowly increased from 1.78 MJ/US\$ (2000) in 2000 to 11.31 MJ/US\$ (2000) in 2008. The projected energy intensity is shown to be non-linear up to 2035. The increasing trend of energy intensity in agriculture sector of Bangladesh does not support sustainable

development. Schaeffer *et al.* 2005, reported that in Brazil the agriculture energy intensity was 3 MJ/US\$-2000 ppp in 1980.

The energy intensity is difficult to estimate and analyze because a large portion of total utilized energy in this agriculture sub-sector comes from human and animal muscle power, mechanical power of agriculture machineries, natural gas in the form of organic fertilizer and traditional energy, namely biomass in the form of bio-fertilizer. It is not easy to translate human and animal muscle power, mechanical power of machineries, organic and bio-fertilizer into economic values. The energy intensity in terms of final commercial energy in the form of electricity, gas, petroleum and coal in agriculture sector can be explained easily because of available data and information about the sectoral energy consumption in our national statistics. In order to examine the long-term economic aspect of energy in this sub-sector, it is necessary to compare the energy intensity in terms of all kind of energy and power used.

The estimated historical energy intensity for the period 1990 to 2008 of agriculture sub-sector in terms of total final energy is shown in Fig. 1b. It is realized from the calculated data that the historical energy intensity slowly increased from 2000 to 2005, which was 10.06 to 17.59 MJ/US\$ and it was 20.11 MJ/US\$ in 2008. The gradual incremental growth of intensity is due to the growth of final energy consumption through introduction of machineries for cultivation, electricity and petroleum products for irrigation. The pattern of energy intensity of Fig. 1b further indicates that the growth of energy demand in this sector will enhance the productivity of crops and other agriculture products. Thus, the sector may contribute significantly in the overall economy of the country in the long-term future.

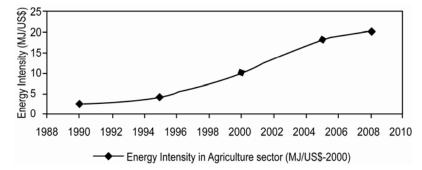

Fig. 1b. Energy intensity scenario in agriculture sub-Sector (crops and horticulture) of Bangladesh with commercial energy used.

The estimated energy intensity in terms of all kinds of energy used in agriculture subsector is shown in Fig. 1c. In this calculation, we have simply converted all kinds of energy such as muscle power, mechanical power, chemical and bio-fertilizer energy (excluding pesticide, seed and water energy) and all other forms of final commercial energy (petroleum, electricity and gas) used in irrigation, into MJ unit, shown in Table 2. It has been realized that the energy intensity increased linearly from 45.67 MJ/US\$(2000) in 1990 to 54.47 MJ/US\$(2000) in 1995. After 1995 the energy intensity decreased and in 2000 it was 51.53 MJ/US\$(2000), again increased slowly and in 2005 it was 54.47 MJ/US\$(2000). The calculated energy intensity shows that economic growth of agriculture (production of crops) has been achieved sustainability. The compound growth of energy demand for a long-term basis will not accelerate economic growth of this sub-sector.

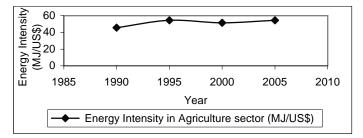

Fig. 1c. Energy intensity scenario in agriculture sub-Sector (crops and horticulture) of Bangladesh with all kind of energy (muscle power, machinery energy, fertilizer energy, petroleum, electricity, gas and coal) used.

The mechanical power of machineries will gradually replace the muscle power of human and animal shown in Table 2. As a result, the required number of labor force for this sub-sector is decreasing day by day. In the year 1990, the labor force in agriculture sector was 66% of the total labor of the country, which stood 48% in the year 2005 (BBS-1992-2008, LFS 1996-2006), shown in Table 1. Due to the decline in number of labor force in agriculture sector, the contribution of human muscle power in total energy supply has decreased to 4% in the year 2005 compared to 8% in the year 1990. On the other hand, the contribution of the mechanical power to the total energy supply in agriculture sector was about 4.3% in 1990, which increased to about 10.3% in the year 2005 (LS 1998-1999, AC 1996). The introduction of machinery in agriculture drastically relaxed the required number of labor force that helps in improving the productivity of the sector and improving the quality of life of rural people.

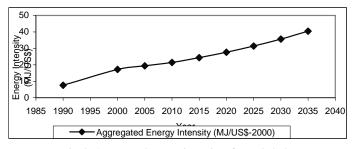

Fig. 2. Aggregated energy intensity of Bangladesh.

Aggregated energy intensity: The aggregated energy intensity (agriculture, industrial, transport and service) is calculated based on historical data from 1990 to 2008; and it is

projected from 2009 to 2035 for the historical compound economic and energy growth of the country. The estimated aggregated energy intensity is shown in Fig. 2. The energy intensity was 7.6 MJ/US\$ (2000) in 1990 and rose to 19.39 MJ/US\$ (2000) in 2005.

The energy intensity increased to 40.64MJ/US\$ (2000) in 2035. In Bangladesh, Hossain (2005), reported aggregated energy intensity as 10.56 MJ/US\$ (2.36 MJ/US\$-PPP) in 2004. The intensity has increased slightly over the years and it becomes only about twofolds in the year 2035 compared to 2000. The redeeming feature of low energy consumption with respect to its GDP is that the country's energy intensity is very low, which is lower than most of the developing countries. This is probably because there would not be any significant structural change in the country's economy over the study period. On the other hand, the energy intensity shows an increasing tendency over the whole projected period and this open-ended increasing tendency could not support sustainable development of the country.

Mechanization index, energetic efficiency and energy productivity in agriculture: The energy input and output from various sources are calculated on the per hectare basis. The performance indicators/parameter are shown in Tables 2 and 3. It is observed that the cultivable area is reducing day by day. The output as product and by-product depends on

	1990 (GJ/hectare)	1995 (GJ/hectare)	2000 (GJ/hectare)	2005 (GJ/hectare)
Total crop area (Thousand hectare)	14060	13520	14270	14107.28
Available human energy input	1.05	1.33	0.62	0.72
Available animal energy input	0.16	0.17	0.18	0.183
Available machinery energy input	0.69	1.00	1.55	2.52
Irrigated energy input	2.31	3.29	3.94	4.89
Total physical energy (1+2+3+4)	4.21	5.79	6.29	8.313
Organic fertilizer (livestock residue) energy input	5.26	5.42	5.04	5.08
Fertilizer (chemical) energy input	6.33	8.01	9.45	11.29
Pesticides energy input	0.09	0.12	0.19	0.27
Total chemical energy input (GJ/hector) (7+8)	6.42	8.13	9.64	11.56
Seed energy input	0.97	0.98	0.93	0.71
Water energy input	1.08	1.15	1.37	1.44
**Total input energy (without solar energy)	17.94	21.47	23.27	27.10
Solar energy input	65130	65130	65130	65130
Total energy input (with solar energy)	65148	65151	65153	65157
Food production (Tone/hector)	2.20	2.31	2.72	2.98
Food energy output	23.82	24.6	30.12	30.54
Agriculture residue energy output	46.05	49.95	48.70	51.54
Total energy output	69.87	74.55	78.82	82.08

Table 2. Energetic parameter in Bangladesh agriculture.

the level of energy input. It is found that the input as muscles power did not increase in the study period. However, the input as physical power significantly increased during the same period due to only the mechanical energy input for tillage operation. It is seen that the contribution of mechanical (tractor, power tiller) energy was 16% of the total physical energy in 1990 and it rose to 30% in 2005 as shown in Table 2. Rapid growth of mechanical energy input has made a significant contribution to the total draft energy.

Table 3. Energetic parameter and index in Bangladesh agriculture.

	1990	1995	2000	2005
GDP from agriculture (million US\$-2000)	4850	4702	5737	6388
Energy intensity (MJ/US\$-2000) (excluding- pesticide, water, seed and				
solar energy)	45.67	54.47	51.53	54.47
Energetic efficiency (only commercial energy input)	3.96	3.49	3.39	3.03
Energetic efficiency (commercial energy and solar energy input)(%)	0.109	0.114	0.121	0.126
Energy productivity (Kg/MJ)	0.12	0.10	0.11	0.11
Mechanization index (%)	63.9	68.5	75	78

In 1990 the draft energy including animal energy and mechanical energy was 0.85 GJ/hectare and it increased to 2.703 GJ/hectare, which has a significant contribution to producing agricultural output. In 1990 the mechanization index was 63.9% and raised to 78% in 2005 that is a 22% increment compared to 1990, shown in Fig. 3. In Bangladesh, Alam *et al.* (2005), reported a mechanization index of 86% in 2000. Due to government's policy, a large number of tractor and power tiller were imported and significant draft power became available.

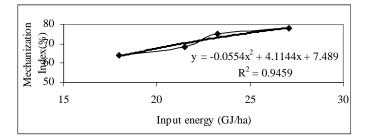

Fig. 3. Relation between total energy input (GJ/hectare) and mechanization index (%).

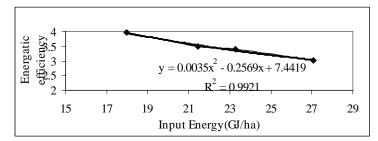

Fig. 4. Relation between total energy input (GJ/hectare) and energetic efficiency.

Thus the physical power input level improved significantly as also reported by Alam et al. (2005). The mechanization index increases with increasing energy input/hector and

has a tendency to reach the saturation level. It was observed at the beginning of the study period that the share of fuel energy (electricity and diesel) in total physical energy input was 71%, where the share of muscle energy obtained from human and animal was 29%. At the end of the study period, the share of that fuel energy (electricity and diesel) consumption reached 89%. However, there was an increasing consumption of electricity and diesel oil, which significantly contributed to improving the input energy level and consequently an increase in output.

It is seen from Table 2 that the fertilizer energy input increased rapidly in comparison with physical energy input. The fertilizer energy input rose from 6.33 to 11.29 GJ/hectare during the study period. In addition, energy input from pesticide and water increased uniformly over the study period and seed energy is nearly constant during this time. Table 2 shows that the fertilizer energy input was increased 1.21-fold during 1990 -1995, 1.24-fold during 1995 - 2000 and 1.18-fold during 2000 - 2005. On the other hand, output energy practically did not change during 1990 - 1995, and were slight increasing 1.12-fold during 1995 - 2000 and 1.03-fold during 2000 - 2005. The result shows that during 1995 - 2000, fertilizer-input energy increased to the highest level and the output energy also increased accordingly in the same period. At the end of the study period, it is observed that the incremental fertilizer energy input is rather insensitive in producing increased energy output, and the energy input for irrigation increased linearly.

In the study period the energetic efficiency (only commercial energy) was 3.96 in 1990 and it was 3.03 in 2005. Alam *et al.* (2005) calculated the energetic efficiency for wheat was 8 in 2000 in Bangladesh. The Fig. 4 shows that the energetic efficiency declined with increasing energy input. This indicates that input energy increased faster compared to output energy. The energetic efficiency (both commercial and solar energy) increased with increasing energy input/hector. So there is enough scope still open to achieve greater solar conversion efficiency through photosynthesis. At present, the conversion efficiency achieved is 0.126% in Bangladesh agriculture, where the achievable conversion efficiency is evaluated as 1% (Alam *et al.* 2005).

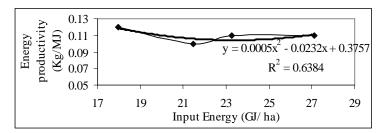

Fig. 5. Relation between total energy input (GJ/hectare) and energy productivity (Kg/MJ).

Fig. 5 shows the relation between total energy input (GJ/hector) and energy productivity (Kg/MJ). In 1990 the production of food was 2.20 tone/hectare and in 2005

it rose to 2.98 tone/hectare i.e. 35% increase in the study period. On the other hand the input energy was 17.94 GJ/hectare in 1990 and rose to 27.10 GJ/hectare in 2005, i.e. the input energy increased 51% in 2005 with respect to 1990.

In 1990 the energy productivity was 0.12 and declined to 0.11 in 2005. This means that 0.11 grain output was obtained per unit energy. The energy productivity declined with increasing energy input/hectare and it can be concluded that our agriculture sector is going to its saturation level.

CONCLUSIONS

Firstly, it has been realized that the energy intensity (considering total agriculture and commercial energy only) increased by 6.35-fold from 1990 to 2008. The projected energy intensity is shown to be non-linear up to 2035. The increasing trend of energy intensity in agriculture sector of Bangladesh does not support sustainable development.

Secondly, it has been realized that the energy intensity (considering crops and horticulture sub-sector and commercial energy only) increased by eightfold from 1990 to 2008. The pattern of energy intensity indicates that the growth of energy demand in this sector will enhance the productivity of crops and other agriculture products.

Thirdly, it has been realized that the energy intensity (considering crops and horticulture sub-sector with commercial and non-commercial energy) increased by 1.19-fold from 1990 to 2005. The calculated energy intensity shows that sustainability in respect of economic growth of agriculture (production of crops) is attainable.

In the first case, the energetic efficiency, where only the commercial energy is included, decreased from 3.97 to 3.03 in the study period. This declining tendency with increasing energy input indicates that input energy increases faster compared to energy output. In the second case, the energetic efficiency, where both commercial and solar energy is included, increased from 0.109 to 0.126% in the study period of 1990 to 2005. This shows that there is enough scope still open to achieve greater solar conversion efficiency through photosynthesis.

The contribution of mechanical (tractor, power tiller) energy was 16% of the total physical energy in 1990 and it rose to 30% in 2005. In 1990 the mechanization index was 64% and rose to 78% in 2005 showing a 22% increment compared to 1990.

The production of food increased by 35% in the study period. On the other hand the input energy increased by 51% in 2005 with respect to 1990. In 1990 the energy productivity was 0.12, which declined to 0.11 in 2005. The energy productivity declined with increasing energy input/hectare.

It can be concluded that our agriculture sector is approaching to its saturation level in the present trend, unless there is new innovation in agriculture.
