Intractable Temporal Lobe Epilepsy from Benign and Malignant Amygdalo-hippocampal Anglioglioma; Icroneurosurgical Management. A Report of Two Cases with Short Literature Review

FH CHOWDHURYa, MR HAQUEb, NC SHAHAc, KA KAWSARD

Summary:
Epilepsy patients are usually managed medically but some cases are resistant to medical treatment and needs surgical treatment. Temporal lobe epilepsy (TLE) is commonly intractable. The underlying cause may be mesial temporal sclerosis (MTS), cortical dysplasia (CD), tumors (ganglioglioma, dysembryoplastic neuroepithelial tumor-DNET), post traumatic gliosis, infection (tuberculosis) parasitic infestation (schistosomiasis, neurocysticercosis) etc. In this type of epilepsy surgery is the treatment of choice (even there is no symptoms other than seizure). Here we report two cases of surgically treated TLE that were due to low grade ganglioglioma and high grade ganglioglioma. In both cases the only presenting symptoms was complex partial seizure (Psychomotor epilepsy) for which they underwent scalp EEG (Electro Encephalography) and MRI (Magnetic Resonance Imaging) of brain. Both patients were managed by complete tumor excision with amygdalohippocampectomy plus standard anterior lobectomy. One patient with high grade ganglioglioma recurred within two months of operation and expired within five months. The other case was seizure and disease free till last follow up.

Key Word: Ganglioglioma, Intractable temporal lobe epilepsy, Amygdalohippocampectomy, Lesionectomy.

CASE REPORTS

Intractable Temporal Lobe Epilepsy from Benign and Malignant Amygdalo-hippocampal Anglioglioma; Icroneurosurgical Management. A Report of Two Cases with Short Literature Review

Introduction:
About 20%-30% epilepsies are drug resistant and intractable.1,2 In this group of patient some form of surgery is usually needed either to cure epilepsy or to improve living standard by better control of epilepsy with drugs. The idea of surgical treatment for epilepsy is not new. However, widespread use and general acceptance of this treatment has only been achieved during the past three decades. Improvements in imaging resulted in an increased ability for preoperative identification of intracerebral and potentially epileptogenic lesions.3 High resolution magnetic resonance imaging plays a major role in structural imaging. EEG (Especially video) and other functional imaging usually help in identification of epileptogenic zone or foci2. Today, epilepsy surgery is more effective and conveys a better seizure control rate. It has become safer and less invasive, with lower morbidity and mortality rates3.

Here we report our initial experience of epilepsy surgery (amygdalohippocampectomy) with two medial temporal lobe tumor (ganglioglioma) in Bangladesh.

Case presentation:
Case 1
A 11 year old right handed school girl presented with sudden development of uneasiness, perception of smell of kerosene, followed by loss of awareness of surroundings for a period of 1-2 minutes for last 20 months. Initially the episode of seizure was 3-4 attack per week but later it was 10-12 attack per day. She was on adequate doses of two anti epileptic drug (AED) (Carbamazipine and sodium valproate) for last 16 months but seizure frequency was not reduced rather increased. She was on adequate doses of two anti epileptic drug (AED) (Carbamazipine and sodium valproate) for last 16 months but seizure frequency was not reduced rather increased. She was on adequate doses of two anti epileptic drug (AED) (Carbamazipine and sodium valproate) for last 16 months but seizure frequency was not reduced rather increased. She was on adequate doses of two anti epileptic drug (AED) (Carbamazipine and sodium valproate) for last 16 months but seizure frequency was not reduced rather increased. Abstract:
Epilepsy is a common neurological disorder characterised by recurrent seizures. Temporal lobe epilepsy is the most common type of epilepsy, accounting for over 50% of all cases. It is often idiopathic or symptomatic, arising from a focal abnormality in the temporal lobe. The most common causes of symptomatic temporal lobe epilepsy include mesial temporal sclerosis (MTS), cortical dysplasia (CD), tumors (ganglioglioma, dysembryoplastic neuroepithelial tumor-DNET), post traumatic gliosis, infection (tuberculosis), parasitic infestation (schistosomiasis, neurocysticercosis) etc. In this type of epilepsy surgery is the treatment of choice (even there is no symptoms other than seizure). Here we report two cases of surgically treated TLE that were due to low grade ganglioglioma and high grade ganglioglioma. In both cases the only presenting symptoms was complex partial seizure (Psychomotor epilepsy) for which they underwent scalp EEG (Electro Encephalography) and MRI (Magnetic Resonance Imaging) of brain. Both patients were managed by complete tumor excision with amygdalohippocampectomy plus standard anterior lobectomy. One patient with high grade ganglioglioma recurred within two months of operation and expired within five months. The other case was seizure and disease free till last follow up.

Key Word: Ganglioglioma, Intractable temporal lobe epilepsy, Amygdalohippocampectomy, Lesionectomy.
of disease. On complete, physical, neurological examinations including mental functions (neuropsychiatric evaluation) revealed no abnormality. Repeated scalp EEG recording showed epileptic spikes originating from right centro-temporal region. MRI of brain in epilepsy protocol showed features of right amygdalo-hippocampal mass lesion (1x1.5x1cm) suggestive of low grade glioma (Fig.-1 A&C).

She underwent complete tumor removal with amygdalohippocampectomy and standard anterior temporal lobectomy through right temporal craniotomy and trans middle temporal gyrus approach. Histopathological examination revealed grade-1 ganglioglioma. Postoperatively she recovered uneventfully. She was put on carbamazipine 100mg tablet thrice daily that was tapered and stopped 4 months after operation. She has been seizure free for last eighteen months. Post operative MRI of brain at the end of 4th months after operation showed no residual or recurrent tumor (Figure1B&D) and there was no visual field defect or neuropsychiatric deficit.

**Case 2:**

A forty one years old right handed cultivator presented with history of sudden onset uneasiness followed by smell of rotten meat for a period of 10-15 sec for last 2 months with 7-8 episodes of these events per day. He had no headache, vomiting, visual disturbances, limb weakness or gait disturbances. On neurological examinations including mental functions were normal except left sided extensor planter and positive Hoffman signs. Other physical and systemic examinations revealed no abnormality. Scalp EEG recording showed epileptic spikes originating from right centro-temporal region. MRI of brain showed features of right amygdale and hippocampal mass lesion (2x1.5x1cm) suggestive of glioma that was compressing right cerebral peduncle (Fig.-2 A&B).

He underwent amygdalohippocampectomy with lesionectomy plus standard anterior temporal lobectomy through right temporal craniotomy and trans middle temporal gyrus approach. Histopathology revealed grade-3 (anaplastic) ganglioglioma. Postoperatively he developed left sided hemiparesis due to operative site hematoma showed on immediate post operative CT scan of brain (Fig. 2C) that recovered within seven days. She was put on carbamazipine 100mg tablet thrice daily and advised for radiotherapy but patient party refused radiotherapy. He was seizure free for 02 months but after that the seizure events returned along with left sided weakness and features of raised intracranial pressure. Post operative MRI of brain at the end of 4th months showed huge recurrence of tumor(Figure2D). The patient expired five months after operation.
Discussion:

Intractable epilepsy patient is a burden for the patient himself, family & society and also to physician. Where indicated a properly done surgery can cure epilepsy or at least alleviates patients lifestyle with better control of seizure by drugs. William MacEwen (1848–1924) and Victor Horsley (1857–1916) in London were the first to localize and remove epileptogenic lesions, as identified by their symptomatogenic zone, according to the pioneering work of John Hughlings Jackson (1835–1911). The first epileptic surgery done by Sir Victor Horsley in 1887 was a case of intractable epilepsy from post traumatic gliosis. After a long dormant stage epilepsy surgery developed tremendously in last three decades. Among the drug resistant intractable epilepsy, temporal lobe epilepsy is the commonest epilepsy (about 80%) and it responds beautifully to surgery. Common causes of intractable surgical epilepsy are cortical dysplasia (CD), MTS, temporal lobe and other lobe tumors (DNET, ganglioglioma and other), cortical atrophy, stroke, trauma, vascular lesion (AVM, cavernoma) etc. EEG (especially video EEG) and good quality MRI are enough for identification of epileptogenic lesion, zone or focus. Only in a few number of cases fMRI (Functional MRI), PET (Positron Emission Tomography) or SPECT (Single Photon Emission Tomography) are needed to aid in localization.

Common surgical procedure for temporal lobe epilepsy are anterior temporal lobectomy (ATL), amygdalohippocampectomy (AH) through middle or inferior temporal gyrus approach (Transcortical), trans-sylvian selective amygdalohippocampectomy, trans middle temporal gyrus standard ATL +AH, focal cortical excision in cortical dysplasia (CD). In temporal lobe epilepsy surgery amygdale is excised with hippocampus even though amygdale is not diseased in most of the cases as it decreases the electrical threshold of TLE and potentiate in generation of epilepsy.

In case-1 the patient was suffering from intractable TLE. Imaging confirmed a epileptogenic lesion in the amygdala and hippocampal area which was a low grade ganglioglioma. Low grade ganglioglioma is one of the common benign lesions in this area causing TLE especially in children for which surgery is needed. Appropriate surgical intervention is usually curative for both epilepsy and tumor. In case-2 anaplastic ganglioglioma in amygdale and hippocampus is less common cause of TLE. When occurs, presentation may be with epilepsy but clinical features progress quickly. Surgical treatment confirms histopathology along with palliation of symptoms. Radiotherapy improves a little. Symptoms recur along with other features suggestive of rapidly growing mass in intracranial space which is usually fatal.

We went for amygdalohippocampectomy with lesionectomy plus standard anterior temporal lobectomy in both cases but selective amygdalohippocampectomy with lesionectomy could be another surgical option to these lesions. Size of the lesion, possibility of different pathology, narrow space through trans-sylvian rout and possibility of manipulation and damage of critical vessel and neural structures and most importantly less familiarity of the approach along with less success rate of amygdalohippocampectomy in controlling epilepsy helped us to take decision in favor of trans middle temporal gyrus approach amygdalohippocampectomy with lesionectomy plus standard anterior temporal lobectomy instead of selective amygdalohippocampectomy in the hope to cure epilepsy as well as the lesion. It has been suggested that the amount of tissue resected in mesio-temporal operations is crucial for surgical success in mesial TLE. Middle temporal gyrus approach does not usually damage the optic radiation (Meyer loop) unless excessive backward and upward retraction or misdirection of transcortical incision. In all of our cases we found no visual field defect both clinically and in perimetry.

Generally, complication rates of epilepsy surgery are relatively low and thought to be acceptable, with approximately 1 to 2% permanent morbidity. The rate of minor complications was 3.6%, and the rate of major complications was 1.26% in the Zürich series of 478 amygdalohippocampectomies. Persisting hemiparesis occurred in 0.84% as a result of choroidal infarcts of the internal capsule. Typical neurological complications after surgery for TLE include temporary dysphasia or hemiparesis as caused by manipulation-induced brain swelling or brain contusion, small vessel infarction, and hemorrhage. There are the classic surgical problems such as infection, thrombosis, etc., in the range...
of 2 to 4%, which rarely cause permanent damage.\textsuperscript{14} The mortality rate is clearly below 1% in most series. In our case-2 post operatively patient developed transient hemiparesis that was due to haematoma in the operative field compressing one of the crus cerebri. About 70% patients become seizure free after temporal lobe epilepsy surgery and another 15-25% patient will have at least a 90% reduction in seizure frequency.\textsuperscript{2} Seizure control rate in MTS after surgery is excellent.\textsuperscript{3,4} In certain developmental tumors, e.g., gangliogliomas and dysembryoplastic neuroepithelial tumors, which can be treated with excellent seizure-control rates in most patients.\textsuperscript{16} Also, certain types of low-grade gliomas (e.g., isomorphic subtype of low-grade astrocytoma, pilocytic astrocytoma) can be operated on with excellent results.\textsuperscript{17-20,21} In a series limited to preoperatively tailored resections for lesional (nonsclerotic) mesial TLE, satisfactory seizure control was obtained in 86% of patients.\textsuperscript{22} Outcome with lesionectomy and corticectomy was excellent, especially when a tumor was present (95% satisfactory seizure control).\textsuperscript{23} Although it depends more on patient selection than surgery, it should be noted that operating on children and adolescents with epilepsy is extraordinarily promising with respect to seizure control and neuropsychological and psychosocial outcomes.\textsuperscript{5,24-27,28}

\textquoteleft Engel grading\textquoteright{} system is used for assessment of outcome of epilepsy surgery. For effective initiation and implementation of epilepsy surgery program by a team formed of epileptologist, neuropathologist, neuropathologist, neuroradiologist and neurosurgeon the facilities of EEG (especially video EEG), MRI and sometimes other imaging facilities along with cooperation from other specialty are very essential.
