CASE REPORTS

Transient Acute Myeloid Leukemia in a Newborn with Down’s Syndrome

ZSM HAQUEa, NJAHANb, BK RAHAc, M HASANd, M BEGUME, AWS ROBf,
SYASMING, SKA HASNATH, TFARHANAI

Summary:
We report the case of a newborn with Down’s syndrome associated with transient acute myeloid leukemia (AML). The leukemic presentation resolved spontaneously without treatment just 4 weeks after birth. A 2 days old newborn presented with respiratory distress, lethargy, poor suck and mild hepatosplenomegaly with features of Down’s syndrome. Total white cell count was 144,000/cmm with blasts 92%. Other Septic work up was negative. Peripheral blood smear revealed hyper leukocytosis and presence of blast cells. Flow cytometric analysis revealed acute myeloid leukemia. The peripheral blast cells persisted for 4 weeks, after which the hemogram and the differential WBC count returned to normal and a final diagnosis of transient acute myeloid leukemia was made. Only few cases of congenital leukemia with Down’s syndrome have been reported in the literature. In Down’s syndrome, AML whether transient or not, generally shows cytogenetic and molecular aspects that differ from those of adult acute leukemias.

Key words: Down’s syndrome, Transient myeloproliferative disease, Transient leukemia.

(J Bangladesh Coll Phys Surg 2016; 34: 213-217)

Introduction:
Down’s syndrome (DS) or constitutional trisomy 21 was linked to leukemia for the first time in a case report published in 19301. The incidence of acute leukemia in patients with DS is 14 times higher than in unaffected children, and the disease is mainly myelogenous2. Transient abnormal myelopoiesis is almost unique to Down’s syndrome, and probably occurs in about 10% of newborn infants. Because the leukemic picture resolves spontaneously, the disorder has been called transient myeloproliferative disorder (TMD), transient blastemia, or transient abnormal myelopoiesis. Now the disease is commonly referred to as “transient leukemia” (TL). Typically, TL is diagnosed in clinically normal children with DS via the casual detection of leukocytosis with circulating blast cells. The characteristic feature of transient leukemia in DS patients is that the TL disappears on its own without treatment in just a few months. The typical and persistent spontaneous remission of the leukemic presentation in 4 to 6 weeks suggests a transient disruption of the granulocytopoietic system3. The TMD is a clonal disease characterized by accumulation of immature megakaryoblast in fetal liver and peripheral blood, a picture indistinguishable from AL4, 5, 6. We report the case of Down’s syndrome with transient acute leukemia presented in NICU at Ad-din Medical College Hospital.

Case Report:
A term female baby born to 25 years old mother of non consanguineous marriage by Lower Segment Cesarian Section (LUCS) due to maternal Gestational Diabetes Mellitus (GDM). There was no history of cytotoxic drug intake or exposure to radiation during antenatal period. Special emphasis was given to elicit the history of maternal fever, rash or lymphadenopathy in the

mother in the first trimester to rule out intrauterine infection. Her birth weight was 3.3 kg, and APGAR score was 8/10 and 9/10 at one and five minutes respectively. On 2nd day the baby developed difficulty in breathing. Her respiratory rate was 70/min, Heart rate was 180/min, no cyanosis was observed and SpO₂ >95% with 2L O₂ by nasal cannula, and temperature was within normal limit. No lymph nodes were palpable. Physical examination revealed features of Down's syndrome (dysmorphic facies, epicanthic folds, hypotonia, and simian crease in hands). She was tachypnic, berath sound vesicular with no added sound. Her blood pressure of all four limbs were within normal limits, there was a systolic murmur over left lower sternal area. Abdomen was distended with hepatosplenomegaly, Liver was palpable 4 cm from right costal margin at mid clavicular line and spleen was 3 cm below left costal margin. A clinical diagnosis of Down's syndrome with congenital heart disease was made. Total white cell count was 145000/cmm with blasts 92%. Peripheral smear revealed Anisocytic with anisochromic RBC morphology. WBC was increased in number with shift to the left, majority cells were immature mononuclear cells, morphologically resembling blast, Platelet was normal initially then decreased. Flow cytometric analysis reveals acute myeloid leukemia; overall findings are suggestive of acute myeloid leukemia without maturation. Exchange transfusion was done on day 8. Total WBC count was reduced to 37,620/cmm. The infant was followed and monitored without any specific treatment for leukemia. The peripheral blast cells persisted for 4 weeks, after which the hemogram and the differential WBC count returned to normal (WBC- 19,770/ cu mm, Hb 8.2, PC- 68,000/cu mm), and peripheral blast cells disappeared. Respiratory distress improved in course of time with restriction of the fluid and lowering of leucocytes number possibly had affect on improvement of vitals. The case was labeled as Transient Acute Myeloid leukaemia (AML). Karyotyping showed Trisomy 21. Bone marrow morphology and Cytogenetic studies and serial blood counts were suggested. The baby also had congenital heart disease and intestinal obstruction. Surgical consultation was taken for double bubble appearance of the abdominal X-ray and surgical intervention could not be taken due to poor general condition of the baby. We also planned to do the Echo cardiogram which finally could not be performed in our center for the mechanical dysfunction of the machine.

Discussion:
The diagnosis of TMD usually occurs during the first weeks after birth and is observed as hydrops fetalis. The elevated blood count associated with hepatomegaly is the common symptom in an asymptomatic neonate. Infants with TMD can also display occasionally jaundice and bleeding diatheses, respiratory distress coupled with ascites, pleural effusion, signs of heart failure, and skin infiltrates. There is megakaryocytic infiltration and liver fibrosis, likely caused by excess cytokines secreted from the megakaryoblasts. The full clinical TMD may develop only at the second or third week of life. Laboratory tests are significant for either thrombocytosis or thrombocytopenia accompanied by elevated leukocytes with excess of blasts. This findings consistent with our case. The cause of thrombocytopenia after two weeks of life could be due to direct effect of leukemia on the bone marrow of the baby or could be sepsis which was clinically evident with negative blood culture result. Also hypersplenia could have contribution to thrombocytopenia in our case. The differential diagnosis includes leukoerythroblastic reaction associated with prematurity, sepsis, or asphyxia. However, the blasts of TMD usually persist for several weeks, and GATA1 mutations are invariably found. Flow cytometry reveals that blasts are positive for CD34, CD33, CD61, glycophorin A, and often CD7 and CD36. Savasan & Ravindranath (2003) observed that blasts of DS children with AMKL express CD36, in contrast to the low or no expression of CD36 in AML without DS. If 25% of blast cells are not detected, the diagnosis of AMKL can be given by the megakaryocytic markers CD41, CD61 and CD42a. The immunophenotype of the blasts in AMKL is generally similar to TMD, except that the percentage of CD34 cells may be lower in AMKL. In our case flow cytometric analysis reveals CD13, CD33, CD36, CD117, MPO myeloid markers & CD34 & CD45 are positive. Several treatment approaches have been used, including exchange transfusion, leukapheresis, and low dose cytarabine. Exchange transfusion was done in our case. Although baby recovered from leukemia but was expired from sepsis in another hospital at 56 days of age.

Conclusion:
The course of congenital leukemia is one of rapid deterioration and death from hemorrhage and infection. While diagnosing congenital leukemia, the condition of transient leukemia in Down’s syndrome should always be kept in mind as the later entity is associated with complete remission.
