Abstract

Background: Diagnostic validity of different tests for the detection of spontaneous subarachnoid haemorrhage is an important issue. Objectives: The purpose of the present study was to validate 3D-Computed tomographic angiography in spontaneous subarachnoid haemorrhage. Methodology: This cross-sectional study was carried out in the Department of Neurosurgery and Cath Lab of DMCH in collaboration with private diagnostic centre from September 2013 to February 2015 for a period of six (06) months. Adult patients diagnosed as a case of spontaneous SAH based on clinical features and confirmed by plain CT evidence of subarachnoid blood were included as study population. Patients having current history of trauma, poor clinical grade and agitated patient, patient with renal insufficiency, known allergy to ioddinated contrast agent and patients who were not willing participate in the study were excluded from this study. Then both CT angiography and DSA were performed to detect cause of bleeding and to make a treatment planning. In this study DSA was considered as reference standard for evaluation of CTA. Sensitivity, specificity, positive predictive value, negative predictive value and diagnostic accuracy of CTA were calculated per patient basis and per aneurysmal basis. Result: A total number of 37 patients presented with spontaneous subarachnoid haemorrhage were recruited for this study. The mean age of patients was 58.53±7.54 years. Sensitivity and specificity in depicting intracranial aneurysms were, 93.75% and 100% respectively on a per-patient basis. Positive predictive value and negative predictive value of CTA are 100% and 71.43% respectively. CTA had shown 94.59% accuracy in detection of intracranial aneurysm. Sensitivity and specificity in depicting intracranial aneurysms were 94.74% and 100% respectively on a per-aneurysm basis. Positive predictive value and negative predictive value of CTA are 100% and 71.43% respectively. CTA had shown 95.35% accuracy in detection of intracranial aneurysm. Conclusion: In conclusion CTA has high detection capacity of aneurysm among spontaneous subarachnoid haemorrhage patients. Introduction

Early diagnosis and detection of the underlying cause are considered critical in order to favour the prognosis among spontaneous subarachnoid haemorrhage (SAH). Early identification of an underlying ruptured aneurysm and adequate treatment may eliminate the risk of
re-bleeding, which is a major mortality factor. The therapeutic alternatives of a ruptured aneurysm include surgical clipping and endovascular coiling. Intra-arterial digital subtraction angiography (DSA) is considered the imaging gold standard for depicting the presence of an intracranial aneurysm. However, DSA is an invasive imaging modality, with a relatively high cost and carries a small risk of neurological complications. DSA has currently been reported to cause transient or permanent neurological deficits when performed in 1 and 0.5% of patients, respectively. Therefore, the utility of a non-invasive imaging modality that can detect the presence of intracranial aneurysms is of particular clinical significance.

MRA has been an attractive alternative to conventional angiography due to its risk free, noninvasive nature. Added advantages of this technique are its ability to produce images in three dimensions and the ability to produce many projections after a single acquisition, and the technique forms a routine part of an MRI investigation for cerebral aneurysms. However, a variety of artifacts by phase or magnitude variations in the MR signal afflit MRA and has limited its use, especially in preoperative planning of vascular malformations and aneurysms.

Currently, the advent of CTA has been used in the diagnosis and preoperative planning for patients presenting with aneurysmal SAH. It has been suggested that CTA has several advantages over MRA. CTA possesses greater resolution than MRA; CTA is unique in its capacity to display the relationships of arteries and aneurysms to bone, which contributes greatly to preoperative planning for patients presenting with aneurysmal SAH; CTA can be performed in seconds and can be performed immediately after the unenhanced CT has confirmed an SAH.

Indeed, with continued improvements in imaging, hardware and concomitant software enhancements, the sensitivity and specificity of CTA approaches that of DSA. However, whether or not CTA can be used as the sole modality to provide sufficient diagnostic information to guide the management of non-traumatic SAH still needs further clinical evidence.

The present study aims to assess the diagnostic efficacy of CTA in a preoperative clinical setting in patients with SAH with emphasis in detection of aneurysms. The role of CTA included the identification of the bleeding source, the detection of additional vascular abnormalities and the ability of planning a pretreatment therapy. The purpose of the present study was to validate 3D-Computed tomographic angiography in spontaneous subarachnoid hemorrhage.

**Methodology**
This cross-sectional study was carried out in the Department of Neurosurgery and Cath Lab of Dhaka Medical College Hospital (DMCH), Dhaka, Bangladesh in collaboration with private diagnostic centre from September 2013 to February 2015 for a period of six (06) months. Purposive and convenient sampling technique was used to collect the patients. Adult patients diagnosed as a case of spontaneous SAH based on clinical features and confirmed by plain CT evidence of subarachnoid blood were included as study population. Patients having current history of trauma, poor clinical grade and agitated patient, patient with renal insufficiency, known allergy to iodinated contrast agent and patients who were not willing participate in the study were excluded from this study. In the study period all patients of neurosurgery department of Dhaka Medical College who fulfill the inclusion criteria were included in the study. The study was started in neurosurgery ward. Clinical features of the sample were recorded in data collection sheet. Then both CTA and DSA were done in order to detect the cause of bleeding and make a treatment planning. All spiral CTAs were performed on a helical CT Scanner. One-hundred milliliters of non-ionic iodinated contrast medium was given by peripheral electric pump injector at a rate of 4 ml/s. The scanning area was from the level of C1 up to the cranial vault. Therefore, posterior inferior cerebellar arteries (PICAs) was always included in the study regardless their origin. After data acquisition and raw data analysis, further 2D [multi-planar reformation (MPR)], and 3D volume rendered reconstruction was done. The CTA film was interpreted. Four vessels DSA were performed via a femoral approach in DMCH Cath Lab. All DSAs was performed and interpreted by the interventional neurosurgical team. The team was blind about the CTA finding. Ruptured aneurysms were treated either surgically or by endovascular coiling.

CTA results were compared with DSA findings in all cases. Data were analyzed using standard contingency tables. Patients with negative CTA and DSA results were served as true negatives. Patients with positive CTA and DSA results were served as true positives. CTA false negatives were defined as negative CTA results in cases with vessel pathology found by using DSA. If CTA is positive for an aneurysm but DSA is negative, DSA was further evaluated before declaring CTA as false positive. Accuracy, sensitivity, specificity, positive predictive value and negative predictive value
of CTA in the detection of intracranial aneurysms were evaluated using DSA as reference standard. Appropriate data were collected by using a preformed data sheet (annexure-1). All other needed data were collected from history sheet and investigation papers. Data were modified to be compatible to input in SPSS program version- 21. Statistical analysis was performed by using a commercially available statistical package (SPSS version 21; SPSS, Chicago, Ill). Quantitative variables were expressed as mean ± standard deviation, and categorical variables were expressed as frequencies or percentages. When a p value is <0.05, the difference was considered statistically significant. In this study, DSA was considered a diagnostic standard for the evaluation of cerebral aneurysms. Sensitivity, specificity, and accuracy of CT angiography in depicting aneurysms were calculated on per-aneurysm and per-patient basis. Approval from the Institutional review board of DMCH was taken before commencement of this study.

**Results**

A total number of 37 patients presented with spontaneous subarachnoid haemorrhage were recruited for this study after fulfilling the inclusion and exclusion criteria.

| Table 1: Age distribution of the study population |
| Age Group | Frequency | Percent |
| <60 Years | 18 | 48.6 |
| >61 Years | 19 | 51.4 |
| Total | 37 | 100.0 |

The mean age of patients was 58.53±7.54 years; majority age group was 60 to 72 years which was 51.35%. Minimum age was 41 years and maximum age was 72 years (Table 1).

| Table 2: Results of CT Angiography in Depicting Aneurysms as per patient basis |
| CTA Finding | DSA Finding | Total |
| Positive | Negative | Positive | Negative |
| Positive | 30(93.8%) | 0(0.0%) | 30(81.1%) |
| Negative | 2(6.2%) | 5(100.0%) | 7(18.9%) |
| Total | 32(100.0%) | 5(100.0%) | 37(100.0%) |

CT angiography and DSA were both positive in aneurysms in 30 patients on a per-patient basis. CTA and DSA were both negative in 5 cases. However, CTA negative but DSA positive were in 2 cases (Table 2).

| Table 3: Results of CT Angiography in Depicting Aneurysms as per aneurysm basis |
| CTA Finding | DSA finding | Total |
| Positive | Negative | Positive | Negative |
| Positive | 36(94.7%) | 0(0.0%) | 36(83.7%) |
| Negative | 2(5.3%) | 5(100.0%) | 7(16.3%) |
| Total | 38(100.0%) | 5(100.0%) | 43(100.0%) |

CT angiography and DSA were both positive in aneurysms in 36 intracranial aneurysms on a per-aneurysm basis. CTA and DSA were both negative in 5 cases. However, CTA negative but DSA positive were in 2 cases (Table 3).

| Table 4: Diagnostic Validity of CTA for Detection of aneurysms |
| Diagnostic Validity | Patient Basis | Aneurysm Basis |
| Sensitivity | 93.75% | 94.74% |
| Specificity | 100.0% | 100.0% |
| PPV | 100.0% | 100.0% |
| NPV | 71.43% | 71.43% |
| Accuracy | 94.59% | 95.35% |

PPV=Positive predictive value; NPV= negative predictive value

Sensitivity and specificity in depicting intracranial aneurysms were, 93.75% and 100% respectively on a per-patient basis. Positive predictive value and negative predictive value of CTA are 100.0% and 71.43% respectively. CTA had shown 94.59% accuracy in detection of intracranial aneurysm. Sensitivity and specificity in depicting intracranial aneurysms were, respectively 94.74% and 100% on a per-aneurysm basis. Positive predictive value and negative predictive value of CTA are 100% and 71.43% respectively. CTA had shown 95.35% accuracy in detection of intracranial aneurysm (Table 4).

**Discussion**

CTA and DSA are ionizing radiation imaging techniques indispensable for the management of patients with SAH, albeit inducing a radiation risk to the patient. The expected additional benefit in diagnostic performance, with the use of CTA, justifies the additional radiation risk. Performance characteristics of diagnostic methods involve in our case the presence or absence of an aneurysm. While usually DSA is considered the gold standard that other imaging methods ought to be compared against, it exhibited a number of false-negative results when
surgical confirmation was employed. While DSA and CTA combined can provide us with detailed information on the morphological features of the aneurysm, their accuracy can be measured in an undisputed manner only when surgical findings are available.

The present study aims to assess the diagnostic efficacy of CTA in a preoperative clinical setting in patients with SAH with emphasis in detection of aneurysms. In the study period all patients of neurosurgery department of Dhaka Medical College Hospital who fulfill the inclusion and exclusion criteria was included in the study. Then both CTA and DSA were done in order to detect the cause of bleeding and make a treatment planning.

This study group initially included 40 patients with spontaneous SAH. Three patients passed away immediately after CTA scan, thus excluded from the study. Thus there were a total of 37 patients that underwent both CTA and DSA and formed our study group.

The mean age of patients was 58.53(±7.54) years; in a range of 41 to 72 years. In study of Karamessini et al mean age was 49±15 years with age range of 15 to 76 years.

All patients subsequently underwent DSA. All the positive finding revealed in CTA was also detected in DSA. In addition, DSA identified 2 aneurysms in 2 patients who are negative for any abnormality in CTA. Thus out of 37 patients DSA revealed Aneurysm in 32(86.49%) patients, AVM in 02(05.41%) patients and negative findings in 03(8.11%) patients. Out of 32 patients in whom Aneurysm was detected by DSA, 27(85%) patients had single Aneurysm, in 04(12%) patients double Aneurysm found and in 1(3%) patient there were 3 Aneurysm. Thus 38 aneurysms were identified in DSA. In a similar study by Chen et al a total of 92 aneurysms were identified in which 80 patients (93%) harbored one aneurysm and 6 patients (7%) had 2 aneurysms. One of the newly diagnosed aneurysm was in posterior circulation and size was 7 mm and the other one was an ICA aneurysm measuring 4mm from neck to dome. Among the 38 Aneurysm, 11(28.95%) were between 2-5 mm in size, 16(42.11%) were between 6-9 mm in size and 11(28.95%) were ≥10 mm in size. Chen W et al showed CTA for detecting aneurysms <4 mm, between 4 and 10 mm, and >10 mm was 96.0%, 98.1% and 100.0%, respectively, on a per-aneurysm basis. Mean of the size of the aneurysms is 6.75 mm with 2.94 mm standard deviation in a range of 2 to 12 mm.

In this study CTA correctly detected 36/38 aneurysms. CT angiography depicted positive aneurysms in 30 patients on a per-patient basis and 36 intracranial aneurysms on a per-aneurysm basis. Sensitivity and specificity in depicting intracranial aneurysms were, respectively, 93.75% and 100.0% on a per-patient basis and 94.74% and 100% on a per-aneurysm basis. CTA showed very high sensitivity (97.9%), and its specificity was 100.0%. There were 2 aneurysms, which were not detected by CTA. Thus accuracy was 94.59%, with positive and negative predictive values were 100.0% and 71.43% respectively.

Chen et al study showed the sensitivity, specificity, and accuracy of 16-slice CTA for detecting aneurysms were 97.8%, 100.0% and 98.7%, respectively, on a per-aneurysm basis. Karamessini et al study showed the sensitivity of CTA for the detection of all aneurysms versus surgery was 88.7%, the specificity 100.0%, the positive predictive value (PPV) 100%, the negative predictive value (NPV) 80.7% and the accuracy 92.3%. In study of Taschner et al showed sensitivity and specificity for CTA were 100% and 83%, respectively, on a per-aneurysm-basis.

With regard to the location of aneurysms, CTA had a sensitivity of 100% in the detection of aneurysms in the anterior communicating artery and in the middle cerebral artery bifurcation, regardless their size. This observation is in line with the studies of Anderson et al and Velthuis et al, who also suggested that it is safe to operate based on CTA findings alone, in patients having aneurysms in the aforementioned areas. The results indicate a relative poor detection rate in the posterior circulation aneurysms; this limitation of CTA is well recognized by previous studies. That was mainly due to their small size (<4 mm), lobulated shape and attachment to the posterior clinoid process, having similar density values with the bones, which made their discrimination difficult. We also observed that the ability to demonstrate an aneurysm in the cavernous or terminal segment of the internal carotid artery and to differentiate the sac from the surrounding bony structures, blood clots and fibrous tissue, demands a high quality examination and careful analysis of the three-dimensional and axial-source images. There was also a difficulty in patients with multiple aneurysms and in distal-branch aneurysms sited out of the scanning field of view. All these factors influenced sensitivity in a negative manner. Even though the sensitivity values for the detection of intracranial aneurysms regardless their size, favor CTA versus DSA, the apparent difference between them is
not statistically significant \((P>0.05)\). The findings of this study was concordant with previous reports. Donmez et al\(^\text{15,16}\) found that the overall sensitivity, specificity, and accuracy of CT angiography on a per-aneurysm basis were 95.1\%, 94.1\%, and 95.0\%, respectively. In that same series, for aneurysms of less than 3 mm, the sensitivity, specificity, and diagnostic accuracy were 86.1\%, 94.1\%, and 88.6\%, respectively. Tipper et al\(^\text{17}\) reported the sensitivity and specificity of 16-channel CT angiography as 96\% and 100\%, respectively; 51 of 53 aneurysms were detected. Another study with 16-channel multi-detector CT has been reported by Yoon et al\(^\text{18}\). They examined 71 patients with subarachnoid hemorrhage, and the overall sensitivity, specificity, and accuracy of CT angiography on a per-aneurysm basis were 92.5\%, 93.3\%, and 92.6\%, respectively, for both independent readers. For aneurysms of less than 3 mm, CT angiography had a sensitivity of 74.1\% for reader 1 and of 77.8\% for reader 2. White et al\(^\text{19}\) demonstrated a per-patient sensitivity of 92\% and a per-patient specificity of 94\% for the detection of aneurysms, compared with selective cerebral angiography. The per-aneurysm sensitivity was greater for depicting aneurysms larger than 3 mm than for depicting aneurysms 3 mm or smaller (96\% vs 61\%). A recently published meta-analysis\(^\text{20}\) on the detection of intracranial aneurysms with CT angiography also supports our current findings.

Regarding the diagnostic strategy in assessing patients with possible ruptured intracranial aneurysms, the first step is the early clinical assessment and confirmation of SAH with plain CT or lumbar puncture. Immediately afterwards, in the absence of contraindications to contrast material, cerebral CTA should be performed as an easy to carry out method that provides a reliable early diagnosis when positive. When CTA finding is negative but an aneurysm is likely to be present, DSA should be done.

**Conclusion**

In conclusion the sensitivity and specificity of CTA is very high for the detection of aneurysm among the spontaneous subarachnoid haemorrhage patients. Accuracy of CTA is also reported with a very high value. During comparing the CTA in patients and aneurysm basis it has been found that in both cases CTA is very high for the detection of aneurysm. A large scale study should be carried out to avoid the selection bias.
