Heat-Flux Effect on Fluid Flow and Convective Heat Transfer Through a Rotating Curved Micro-Channel

S. C. Adhikari, R. K. Chanda, R. Akter and R. N. Mondal*

Department of Mathematics, Jagannath University, Dhaka-1100, Bangladesh

Abstract

The present paper investigates heat-flux effect and the dissemination of energy in a rotating bent square micro-channel (MC) subject to a temperature gradient between the vertical sidewalls. The flow structure prevailing the problem is solved by applying a highly accurate spectral-based numerical scheme. The flow controlling parameters are the Dean number (0<Dn≤5000) and the Taylor number (-500 ≤ Tr ≤ 2000) for curvature 0.01 and the Grashof number, Gr=1000. After applying the arc-length path continuation technique to obtain steady solution (SS) curves, two branches of SS consisting of 2- to 8-vortex solutions are prevailed for the non-rotating case while a single branch with a symmetric 2-vortex solution is for positive rotation of the channel. Unsteady flow (UF) properties are simulated by the time-average of the solutions, and the transitional behavior is well predicted by contemplating the power spectrum and phase spaces of the solutions. Results manifest that the UF experiences a consequence ‘steady-state → multi-periodic → steady-state’ for no rotation of the channel as Dn is increased. For the rotating case, on the other hand, the flow advances in the scenario ‘steady-state → multi-periodic → steady-state’ for negative rotation and only a steady-state solution for rotation in the positive direction. Streamlines and isotherms of SS and UF for various values of the flow-controlling parameters are obtained. Centrifugal force impacts the fluid mixer, which then assists to turn the flow into chaos and prompts to intensify the convective heat transfer (CHT).

Keywords: Rotating micro-channel; Flow pattern; Unsteady solution; Phase space; Heat transfer.

Introduction

Flow characteristics especially rotating flows and heat transfer (HT) in a rotating system of different geometrical shapes has attracted a lot of attention from prodigious researchers due to plentiful applications in the engineering fields like heating and cooling system, rocket engine, electric generators, solar energy, and many more (Kockmann, 2005; Yi and Bau, 2003; Schonfeld and Hardt, 2004). The qualitative approach in micro-biochips, micro-fuel cells, micro-coolers, and micro-reactors has been increasing at a rapid cognition due to the quick advancements in nanoelectronics and bioengineering. Since the last couple of decades, research conducted in straight or curved MC has revealed that only a few scientific or numerical evaluations of the analysis of flow behavior in curved MC have been done. (Morini, 2004; Yang et al., 2005; Wang and Liu, 2007). Microfluidic systems typically feature laminar flows, as opposed to the conventional flow processes found in macroscopic devices.

*Corresponding author’s e-mail: rmmondal71@yahoo.com
Schönfeld and Hardt’s (2004) work on curved MC showed that the induced secondary flows generate a mixing effect in micro-devices. The simulated results on helical flows by Jiang et al. (2004) verify the predicted mixing results by a series of experimental evaluations.

Rotating flow features are analyzed in three topics which are the steady solution (SS), unsteady solution (US), and CHT. Curved channel with rotation produces two forces; Centrifugal force and Coriolis force, and these forces directly impact the fluid flow and produce spiraling flow which is also called secondary flow (SF). The first evidence was provided by Dean (1927) where the existence of such kind of problem was analyzed and discussed in detail for motion in a curved tube with a circular cross-section. The main result of this analysis was to introduce the SF which was characterized by the Dean vortices, initiated by Dean in 1927. Since then, several enthusiastic researchers have given deep attention to investigating such types of fluids through different geometric shapes for rotation and non-rotation. Several landmark articles on curved duct flows are mentioned here, for example, Selmi et al. (1994), Alfredsson et al. (1989), Barua et al. (1954), Chengand Wu, (1970), Yamamoto et al. (1999), Yanase et al. (2002), Hasan et al. (2022a, 2022b).

Analyzing the bifurcation structure, which includes the SS and its linear stability, is one of the most important characteristics of fluid flow in a curved MC. Selmi et al. (1994) investigated the structure of bifurcation for an incompressible fluid in a rotating curved channel (CC). A 6-cell revolving flow phenomenon was discovered by Yamamoto et al. (1999) in their examination. Later, Mondal et al. (2007) and Adhikari et al. (2021) evaluated how the bifurcation diagram altered as the curvature of a non-rotating CC expanded or reduced and demonstrated the precise affinity to transient behavior and the bifurcation pattern among steady branches. Wang and Liu (2007) performed a computational analysis on a completely branching structure and stability in a bending MC with a square bend to inscribe the ramifications of curvature, initial circumstances, and disturbances. They showed that regardless of duct curvature size, the spiraling flow is always produced in the channel. They observed multiple limiting points and asymmetric branching points in their ten branches of solutions. Other pertinent studies on fluid flow through different geometric circumstances include Chanda et al. (2020, 2021), Yamamoto et al. (2006), Mondal et al. (2014), and Hasan et al. (2019b).

Examining the nonlinear characteristics is important to figure out the unsteady behavior of the flow. Chandratilleke and Nursubyakto (2003) proposed a mathematical method for elucidating the flow characteristics using a variety of geometrical shapes with various aspect ratios. Later, Wang and Yang (2005) investigated the regular oscillations of an incompressible viscous fluid in a curved square channel (CSC) using both numerical and experimental methods, and a comparison of their findings revealed that they were completely consistent. Mondal et al. (2013, 2014) demonstrated the relationship between the UF and the bifurcation structure through linear stability. Through analyzing the oscillating behavior computationally by Mondal et al. (2017), regular and irregular oscillating flows were observed under conditions of symmetry and without symmetry, respectively. The majority of the important publications solely focused on weak rotational speed. Because of these questions to be answered, the current work focuses on how gyration and curvature affect the flow of unsteady fluid in a CRC.
Chandratilleke and Nursubyakto (2003) studied the role of Dean vortices in fostering HT and demonstrated that CC is more capable than that in a straight duct to gain a better knowledge of thermo-fluid dynamics and CHT through CC. The published simulation results of Yanase et al. (2002) and Mondal et al. (2014) show that SFs increase HT in the flow. The numerical method of flow characteristics and HT via a rotating CSC for different curvatures was recently carried out by Hasan et al. (2019a, 2019b). Recently, Roy et al. (2020) applied a method that used Hasan et al. (2019a) to prognosticate hydrodynamic unsteadiness and CHT in a rotating CRC of medium curvature. In this study, we present the numerical analysis of the puzzling flow behavior and energy distribution of fluid flow in a tightly coiled square-shaped micro-channel in a rotating system. Flow pattern as well as US of the flow features with CHT with strong rotational speed is investigated for both co-rotating and counter-rotating cases of the micro-channel.

Mathematical Model

The geometric scheme that is taken into consideration in this present study is shown in Figure 1. We have into account a fully formed 2D viscous incompressible, and thermally active fluid that passes through CSC. The fixed revolving speed of the system is $\Omega_T$. The applied condition to the outside bend of geometry is at high temperature, on the other hand, the inner bend wall is kept at standard room temperature whereas both the upper surface and lower portion of the wall remain adiabatically isolated. It is presumed that a constant pressure gradient controls the fluid flow as shown in Fig. 1.

Fig. 1. Geometry of the problem.
The working equations such as the mass conservation, momentum equation, and energy equation which describe the physical situation of the flow through a revolving duct can be referred to as Chanda et al. (2020, 2021). Those equations are non-dimensionalized by using the following variables,

\[ u = \frac{u'}{U_0}, v = \frac{v'}{U_0}, w = \frac{\sqrt{2\beta}}{U_0} w', x = \left( \frac{x' - 1}{\beta} \right), \bar{y} = \frac{y'}{d}, z = \frac{z'}{d}, P = \frac{P'}{\rho U_0^2}, T = \frac{T'}{\Delta T'}, t = \frac{U_0 t'}{d}, \beta = \frac{d}{L} \]

where, \( U_0 = \frac{v}{d} \) is the uniform velocity. Here, \( d \) and \( v \) are the representative length and the kinematic viscosity respectively. Since our study is a two-dimensional case, so we assumed \( \frac{\partial}{\partial z} = 0 \). Thus, the transform equations are as follows.

Mass conservation equation:

\[ \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \ell \beta u = 0 \quad (1) \]

Navier-Stokes equation:

\[ \frac{\partial u}{\partial t} + \left( v \frac{\partial}{\partial y} + u \frac{\partial}{\partial x} \right) u - \frac{\varepsilon}{2} \ell u^2 = -\frac{\partial P}{\partial x} + \frac{\varepsilon}{Dn} (\Delta_x u - \ell^2 \beta^2 u) \quad (2) \]

\[ \frac{\partial v}{\partial t} + \left( v \frac{\partial}{\partial y} + u \frac{\partial}{\partial x} \right) v = -\frac{\partial P}{\partial y} + \frac{\varepsilon}{Dn} \Delta_y v \quad (3) \]

\[ \frac{\partial w}{\partial t} + \left( v \frac{\partial}{\partial y} + u \frac{\partial}{\partial x} \right) w + \frac{\varepsilon}{2} \ell u w = \ell G + \frac{\varepsilon}{Dn} (\Delta_z w - \ell^2 \beta^2 w) \quad (4) \]

\[ \text{where,} \]

\[ Dn = \sqrt{\frac{2d}{L} \frac{U_0 d}{v}}, \quad \varepsilon = \sqrt{\frac{2d}{L}} = \frac{2\beta}{1+\beta x} (0 \leq \beta \leq 1), \quad G = \frac{\partial P}{\partial z}, \quad \ell = \frac{1}{1+\beta x} \]

Introducing sectional stream function \( \psi \) as follows

\[ u = \ell \frac{\partial \psi}{\partial y}, v = -\ell \frac{\partial \psi}{\partial x}, \text{where} \quad \ell = \frac{1}{1+\beta x} \quad (5) \]

The processing equations for axial flow, secondary flow, and energy equations are as follows

\[ \frac{1}{\ell} \frac{\partial w}{\partial t} + \frac{\partial (w, \psi)}{\partial (x, y)} - Dn + \ell \beta^2 w = \frac{1}{\ell} \Delta_2 w - \beta \ell \frac{\partial \psi}{\partial y} w + \beta \frac{\partial w}{\partial x} \quad (6) \]
Convective heat transfer (CHT) increases, and the contours of the isotherms distribute from the center of the outer layer, which is due to a high-pressure gradient. As seen from Figure 7, the velocity increases in the ows oscillation and the pattern of the secondary flow fluctuate in a certain range. The irregularities of the flow increases. For $3845 \leq Dn$ values and presented for different values of $0 < \beta \leq 5000$, regular and irregular oscillating flows were observed under conditions of symmetry, whereas Branch 2 is made up of a 4- to 8-vortex solution. Finally, the variations of the flow at the mentioned time. A 2-vortex asymmetric solution is remained up to the periodic stage and in general landmark articles on curved duct flows are mentioned here, for example, Selmi et al. (1994) investigated the structure of secondary flow (SF). The first evidence was provided by Dean (1927) where the existence of such kind of phenomenon was discovered by Yamamoto et al. (1978) for an incompressible fluid in a rotating curved channel (CC). A 6-cell revolving flow phenomenon was observed by Yamamoto et al. (1983), regular and irregular oscillating flows were observed under conditions of symmetry, whereas both the upper surface and lower portion of the wall remain adiabatically isolated. It is presumed that the completely formed 2D viscous incompressible, and thermally active fluid that passes through the cooled wall (CW) in Figure 8(a) and for the heated wall (HW) in Figure 8(b). It is noticed from Figure 14(b) shows that there is a substantial augmentation in heat transmission from the heating lateral wall to the fluid.

The no-slip boundary conditions are

$$w(\pm 1, y) = w(x, \pm 1) = \psi(\pm 1, y) = \psi(x, \pm 1) = \frac{\partial \psi}{\partial x}(\pm 1, y) = \frac{\partial \psi}{\partial y}(x, \pm 1) = 0$$

and the conditions for thermally heated walls are

$$\begin{align*}
T &= 1 \text{ at } x = 1, y = y \\
T &= -1, \text{ at } x = -1, y = y \\
T(x, \pm 1) &= x \text{ at } x = x, y = \pm 1
\end{align*}$$

The following symmetry criterion is fulfilled by a class of solutions with respect to $y = 0$.

$$\begin{align*}
y &\Rightarrow -y \\
w(x, y, t) &\Rightarrow w(x, -y, t), \\
\psi(x, y, t) &\Rightarrow -\psi(x, -y, t), \\
T(x, y, t) &\Rightarrow -T(x, -y, t)
\end{align*}$$
Numerical calculation

The spectral approach is employed as a fundamental tool since the current study is entirely focused on numerical computation. The expansion of the polynomial functions \( \phi_n(x) \) and \( \psi_n(x) \), entails the variables in a group of functions comprised of Chebyshev polynomials is represented as

\[
\begin{align*}
\phi_n(x) &= (1-x^2)D_n(x), \\
\psi_n(x) &= (1-x^2)^2D_n(x)
\end{align*}
\]

where \( D_n(x) = \cos(n \cos^{-1}(x)) \) states the Chebyshev polynomial of \( n^{th} \) order. The flow representing parameters is expanded in terms of the expansion functions \( \phi_n(x) \) and \( \psi_n(x) \) as:

\[
w(x, y, t) = \sum_{m=0}^{M} \sum_{n=0}^{N} w_{mn}(t) \phi_m(x) \psi_n(y)
\]

\[
\psi(x, y, t) = \sum_{m=0}^{M} \sum_{n=0}^{N} \psi_{mn}(t) \psi_m(x) \psi_n(y).
\]

\[
T(x, y, t) = \sum_{m=0}^{M} \sum_{n=0}^{N} T_{mn} \phi_m(x) \psi_n(y) + x
\]

where \( M \) is the number of truncations in the \( x \)-direction and \( N \) is the number of truncations in the \( y \)-direction, and \( w_{mn}, \psi_{mn} \), and \( T_{mn} \) are the coefficients of expansion. The collocation points \( (x_i, y_j) \) are taken to be

\[
\begin{align*}
x_i &= \cos \left[ \pi \left( 1 - \frac{i}{M+2} \right) \right], \quad i = 1, \ldots, M+1 \\
y_j &= \cos \left[ \pi \left( 1 - \frac{j}{N+2} \right) \right], \quad j = 1, \ldots, N+1
\end{align*}
\]

where \( i = 1, \ldots, M+1 \) and \( j = 1, \ldots, N+1 \).
Resistance coefficient

The represented quantities of the resistance coefficient \( \lambda \) and the mean axial velocity \( \langle w^* \rangle \) are defined as

\[
\lambda = \frac{4\sqrt{2} \beta Dn}{\langle w \rangle^2} \tag{18}
\]

\[
\langle w^* \rangle = \frac{v}{4\sqrt{2} \beta d} \int_{-1}^{1} \int_{-1}^{1} \bar{w}(x,y,t) \, dy \tag{19}
\]

Nusselt number

The Nusselt number \( (Nu) \) is indexed as horizontal heat transfer by

\[
Nu = -\frac{d^*}{\Delta T^*} \left( \frac{\partial T^*}{\partial x^*} \bigg|_{x=0} \right). \tag{20}
\]

The heat transmission rate from the inner walls to the fluid is not uniform due to temperature differences across the vertical sidewalls. Hence \( Nu \) varies on both heating and cooling sidewalls. We define the Nusselt number for the cooled \( (Nu_{c}) \) and heated \( (Nu_{h}) \) sidewalls for the unstable solutions as follows.

\[
Nu_{c} = \frac{1}{2} \int_{-1}^{1} \left| \frac{\partial T}{\partial x} \bigg|_{x=-1} \right| \, dy, \quad Nu_{h} = \frac{1}{2} \int_{-1}^{1} \left| \frac{\partial T}{\partial x} \bigg|_{x=1} \right| \, dy \tag{21}
\]

where \( \langle \rangle \) is the time-average over a period.

Validation of numerical result

This study's underlying algorithm's precision is guaranteed by grid accuracy. In light of this, it is crucial to evaluate the algorithm's effectiveness. We have shown the validation of numerical exactness by determining heat flux \( (Q) \) and axial flow \( (w) \). The following relationship is used to estimate the error percentage.

\[
\varepsilon_p = \left| \frac{\text{current value - previous value}}{\text{current value}} \right| \times 100 \%
\]

In this study, we consider five grid sizes, \( 16 \times 16, 18 \times 18, 20 \times 20, 22 \times 22, 24 \times 24 \) i.e. \( N = M \). The grid size of \( 20 \times 20 \) was good enough to guarantee the accuracy of the solution as represented in Table 1.
Table 1. Validation of grid resolution.

Results and Discussion

Here, the completely formed 2D viscous incompressible fluid through a curved micro-channel (CMC) is computationally evaluated with rotating and non-rotating cases for curvature $\beta = 0.01$. For the non-rotating case, the Dean number, $0 < Dn \leq 5000$, is the flow-controlling parameter while for the rotating case, the Taylor number, $-500 \leq Tr \leq 2000$, controls the flow. Two cases arise in the present study:

Case I: Non-Rotating channel

Case II: Rotating channel

In the following, SS, time advancement, and HT are discussed, in detail, for the above-mentioned two cases.

Case I: Non-Rotating channel

Structure for Steady Solutions

As investigated by Mondal et al. (2007, 2013) for finding the steady solutions, our study prevailed in two branches of SS for $0 < Dn \leq 5000$, $Gr = 1000$, $\beta = 0.01$ (see Fig. 3). These two branches are called Branch 1 (solid red line) and Branch 2 (solid black line). According to Mondal et al. (2006) discussion, the path continuation approach is used to acquire the SS branches using a variety of initial hypotheses. The velocity of the non-isothermal flow and isotherm is shown in Fig. 4. It is clear that Branch 1 is made up of a sym-
metric 2- to 8-vortex solution, whereas Branch 2 is made up of a 4- to 8-vortex solution. Finally, the variation of velocity concerning grid points in the primary flow is depicted in Figure 5 which gives us the idea of CMC flows heating wall and cooling wall as shown in Figure 2.

Unsteady solutions

By investigating the time-advancement solution for CMC with the heating wall and cooling wall for 0≤Dn ≤3840, as visualized in Fig. 6, the unsteady flow is discovered to have a steady-state solution. Steady-state flow in this region always possesses a 2-vortex solution. The nature of the flow quickly changes to regular oscillation i.e., periodic as Dn increases. For 3845 ≤ Dn ≤ 4700, the unsteady flow (UF) remains in regular oscillation and the pattern of the secondary flow fluctuate in a certain range. The irregularities of the flow arise as seen in Fig. 6 for Dn = 5000. Contours of PF, SF, and thermoprofile are shown in Figure 7 for various Dn at the mentioned time. A 2-vortex asymmetric solution is remained up to the periodic stage and in the chaotic state, a new vortex is produced from the channel's outer wall. This new vortex is called Dean-vortex which is due to a high-pressure gradient. As seen from Figure 7, the velocity increases in the axial direction as Dn increases, and the contours of the isotherms distribute from the center of the outer lateral wall to the inner lateral wall because of the buoyancy force and curvature effect.
Convective heat transfer (CHT)

To explore the CHT from the walls to fluid, we study temperature gradients (TG) which simply can explain the rate of heat at a particular location. The TGs are executed for some specific $Dn$ values and presented for the cooled wall (CW) in Figure 8(a) and for the heated wall (HW) in Figure 8(b). It is noticed from Figure 8(a) that on the CW the temperature difference is \( \frac{\partial T}{\partial x} \) dropped down in the middle region of the duct as $Dn$ increases which are taken place due to the advection of outward SF as well as the influence of centrifugal force. On the contrary, outside the central region, \( \frac{\partial T}{\partial x} \) is increased monotonically, which is resulted from the advection of inward SF and due to the fluid mixing. Besides, \( \frac{\partial T}{\partial x} \) is prolonged at the central portion of the duct on the HW monotonically by the opposite SF in the inward direction.
Case II: Rotating channel

Steady solutions for positive rotation

We have searched the SS branches with the help of the path continuation technique and arc-length method and obtained a single branch of SS which exists in the entire ranges for $\beta = 0.01$. Fig. 9 shows a unique SS branch, where we see that the branch is very simple. In Fig. 10, the contours of PF (up), SF (middle), and temperature profile (bottom) on the SS branch for $\beta = 0.01$ at $Dn = 2000$, $Gr = 1000$, and for various values of $Tr$ are demonstrated, where it is seen that the branch is composed of a symmetric 2-vortex solution. Due to the small curvature, Coriolis, and centrifugal forces, the primary velocity and isotherms only little altered as the rotation is increased. The velocity of the flow in the axial direction over various grid points is also shown in Figure 11 for $Tr = 500$ and $Tr = 2000$ which provides us the scenario of velocity increase in a rotating square channel flow for the heating wall and cooling wall.
Unsteady solutions

We perform the time-dependent solution for $\beta = 0.01$ at $Dn = 2000$ and $Gr = 1000$ for different values of $Tr$. The unsteady solution (US) of the entire domain of the investigated $Tr$ ($0 < Tr < 2000$) gives us the same result as the steady-state with a 2-vortex solution (see Fig. 12 and 13). There is no notable change occurring in the primary flow and temperature distribution and implicit with the secondary vortices.

Convective heat transfer (CHT)

To determine the CHT from the heating wall to the fluid, the influence of positive rotation on the heat-generating mechanism is examined. We compute TG at the CW and HW for this reason. Fig. 14(a) illustrates how the difference in temperature on the HW grows in the central region owing to a slight vibration of the heating wall and varies in other places as a result of the fluid mixing. Figure 14(b) shows that $\frac{\partial T}{\partial x}$ on the CW diminishes in the middle area about $y = 0$ and $\frac{\partial T}{\partial x}$ gradually increases the whole part of the duct except the middle area. The propagation of the SF in an outward direction is what leads to these results around $y = 0$ because of the centrifugal force. These results demonstrate that when $Tr$ rises, there is a substantial augmentation in heat transmission from the heating lateral wall to the fluid.
oscillation and the pattern of the secondary flow fluctuate in a certain range. The irregularities of the flow oscillation i.e., periodic as $Dn$ increases. For $3845 \leq Dn \leq 2000$, unsteady solutions of CMC flows heating wall and cooling wall as shown in Figure 2. The main result of this analysis was to introduce the SF which was characterized by the Dean vortices, predicted mixing results by a series of experimental evaluations. The research demonstrates that when buoyancy force interacts with centrifugal and Coriolis forces Hart impact generating mechanism is examined. We compute TG at the CW and HW for this reason. Fig. 14(a) that on the CW the temperature difference is dropped down in the middle region of the duct.

Convective heat transfer (CHT) result as the steady-state with a 2-vortex solution (see Fig. 12 and 13). There is no notable change occurs among steady branches. Wang and Liu (2007) performed a computational analysis on a completely rotational speed. Because of these questions to be answered, the current work focuses on how gyration and viscosity respectively. Since our study is a two-dimensional case, so we assumed $T_{r} = 500$ and $T_{r} = 1000$ for different values of $Dn = 0$ because of the centrifugal force. These results demonstrate that when $Tr < 0$, the vortices' number falls. In this work, the steady-state solution structure of SF in the light of vortices. Fig. 20 depicts how many vortices can the flow be formed for a given Dean number, $0 < T_{r} < 2000$. Fig. 14. TG for the rotating channel. (a) at the heating wall; (b) at the cooling wall. Negative Rotation: $(\beta = 0.01, Dn = 2000, Gr = 1000, -500 \leq Tr < 0)$.

Here, we studied the transient flow behavior for negative rotation of the curved MC for $-500 \leq Tr < 0$, $Dn = 2000$, $Gr = 1000$, and $\beta = 0.01$. Fig. 15(a) and 15(b) show that the UF is a steady-state with a 2-vortex solution for $Tr = -10$. When $Tr = -250$ then we see that the UF is multi-periodic with a 2- to 4-vortex solution (see Fig. 16 and 18). Fig. 17(a) and 17(b) demonstrate the phase-space diagram and spectrum density analysis for conformation of the multi-periodicity flow. Next, we investigate the UF for $Tr = -500$ where it can be

Fig. 15. (a) Transient solution for $Tr = -10$, (b) contours of PF (top) SF (middle), and temperature profile (bottom) for $Tr = -10$.

Fig. 16. Transient solution for $Tr = -250$ and $\beta = 0.01$ at $Dn = 2000$.

Fig. 17(a). Phase space (b) Power spectrum density for $Tr = -250$ and $\beta = 0.01$ at $Dn = 2000$. 
visible that the UF returned to the previous state i.e., the steady-state but the remarkable scenario is that the UF is composed of a 4-cell solution (Fig. 19). The interaction among centrifugal, Coriolis, and buoyancy forces results in the formation of these vortices.

\[ \text{Vortex diagram in the plane} \]

We demonstrate the structure fluctuation of secondary vortices for various parameters of \( Tr \) to observe the structure of SF in the light of vortices. Fig. 20 depicts how many vortices can the flow be formed for a specific value of curvature at a Taylor number and a two- to eight-vortex solution is discovered in the secondary flow pattern for distinct values of \( Tr \). It has become possible to figure out maximum 8-vortex solutions for curvature \( \beta = 0.001 \), compared to 4- and 2-vortex solutions for \( \beta = 0.1 \) and \( \beta = 0.5 \) correspondingly. It is revealed that when \( Tr \) rises, the vortices’ number falls. In this work, the steady-state solution has been discovered to have 2-vortex solutions, the periodic solution has 2- to 4-vortex solutions, and the chaotic solution has 2- to 6-vortex solutions. Due to the fact that chaotic solutions generate a large number of vortices in the surrounding concave wall, it is suggested that they be used instead of steady-state or periodic solutions to enhance heat transmission.
Conclusions

In the present study, the heat-flux effect and the dissemination of energy through a bent MC are determined using a spectral-based computational scheme for rotating and non-rotating cases with a temperature gradient between the vertical lateral walls. From the present study, the following outcomes are listed:

- For non-rotating case, two asymmetric SS are revealed with 2- to 8-vortex solutions. The nonlinearity of the time-advancement flow demonstrates as ‘steady-state periodic chaotic’ which consists of a 2- to 4-vortex solution.
- For positive rotation, an asymmetric SS branchis found with a 2-vortex solution. The nonlinearity of the time-advancement flow is ‘steady-state’ only and consists of a two-vortex solution.
- By analyzing non-linear behavior for negative rotation, the unsteady flow goes through- ‘steady-state-multiperiodic steady-state’ with a 2- to 4-vortex solution.
- CHT is increased significantly with the increase of $Dn$ for non-rotating duct and imposing rotational speed i.e., raising $Tr$ number. Higher $Tr$ leads to the development of the extremely complicated secondary flow field.
- The research demonstrates that buoyancy force interacts with centrifugal and Coriolis forces hart impact the fluid mixing, which then assists to turn the flow into chaos and prompts the intensification of the convective heat transfer (CHT).
