Abstract

Introduction: Oral candidiasis, which is caused by Candida species by the involvement of hard and soft palates, tongue, buccal mucosa, and floor of the mouth, is becoming a very common threat to oral health. Although in the majority of the cases, this infection is caused by Candida albicans which is a normal commensal organism in humans, however, it might be also caused by other Candida species, such as C. glabrata, C. tropicalis, and C. krusei.

Objectives: This study aimed to evaluate the prevalence of oral candidiasis among children and to compare the type of causative candida species among them. Materials and Methods: This prospective observational study was conducted in the Shishu Hospital, Shomoly, Dhaka, spanning January 2016 through December 2016. A total of 286 oral swab samples were collected, and three methods including direct wet mount smear, staining, and culture were used for laboratory investigation of Candida infections. Results: Among 286 respondents, 161 (56.29%) were culturally and microscopically confirmed to have oral candidiasis. Among all of the detected species, C. Albicans was by far the highest species with 139(86.34%) followed by C. tropicalis with 14 (8.68%). Whereas 05(3.12%) cases were infected by C. krusei. On the other hand, the least detected species were C. glabrata and C. guilliermondii with 01(0.62%) and 02(1.24%) respectively. Conclusion: These data accurately and prompt identification of the infectious candida strains is crucial because isolates of Candida species differ extremely, both in their ability to produce infection and also in their susceptibility to antifungal agents.

Key words: Oral candidiasis, Candida species, laboratory investigation.

Introduction:

Over the last few decades, the role of fungi as a causative agent of nosocomial infections in children has been skyrocketed1. These fungi are a major cause of child morbidity, given the increased length of hospital stay also2,3. Oral candidiasis, which is caused by Candida species by the involvement of hard and soft palates, tongue, buccal mucosa, and floor of the mouth, is becoming a very common threat to oral health. Although in the majority of the cases, this infection is caused by Candida albicans which is a normal commensal organism in human4,4 however, it might be also caused by other Candida species, such as C. glabrata, C. tropicalis, and C. krusei4,5. Despite the recent revolution in laboratory techniques, primary diagnosis of invasive candidiasis remains challenging, which causes the delayed detection of candidiasis6. Specific and accurate identification of Candida strains is crucially important, considering the diseases producing ability of the strains and induce susceptibility to the antifungal drugs. Therefore, the present study aimed to evaluate the prevalence of oral candidiasis among children and to compare the type of causative candida species among them.

Material and Methods:

This prospective observational study was conducted in the Shishu Hospital, Shomoly, Dhaka with the ethical clearance of the review board, spanning January 2016 through December 2016. In this study, a total of 286 oral swab samples were collected, and three methods including direct wet mount smear, staining, and culture were used for laboratory investigation of Candida infections. Fresh smear with 20% potassium hydroxide (KOH) and direct microscopic examination with Gram staining of each sample was performed. By the gram stain technique, candidal hyphae and yeasts appeared in dark blue.
Budding yeast was seen by direct microscopy in wet mount preparation. Subsequently, the samples were inoculated aerobically at 37°C for 24–48 hours into Sabouraud dextrose agar (SDA) media with the supplement of chloramphenicol and gentamycin in a screw-capped test tube where Candida produced cream, smooth, pasty convex moist colonies with a distinctive yeast smell. Then the positive cultures were transferred to CHROMagar Candida media for further analysis and differentiation between species based on colony appearance and color following primary culture. The germ-tube test was performed for identifying C. Albicans and to differentiate candida Albicans from non-albicans groups. The test involves the induction of hyphal outgrowths (germ-tubes) when subcultured in fresh human pooled serum at 37°C for 2–4 hours. The wet mount preparation also presented a germ tube which was a hyphal projection without having constrictions at the point of origin from the yeast cell. A commercial Analytic Index (API) yeast indication kit (named API Candida) was used to perform the biochemical test (bioMerieux, Franch) for the isolation of candida sp which was consist of twelve biochemical tests.

Results:
Socio-demographic findings of the study population. A total of 286 patients were included in this study according to the inclusion criteria of the study. Out of those majority, 169 (59.09%) were females whereas, 117 (40.91%) was male patient. By far the highest study population was within the age ranging from 1 year to 05 years with 137(47.90%). The cases gradually reduced with the increase of the age where 87(30.42%) patients were between 6-10 years and 62(21.68%) patients were from 11 to 15 years age group. Regarding the parent’s income level, low socio-economic condition patient was by far the highest number with 217(75.87%) followed by middle socio-economic and higher socio-economic groups with 66(23.08%) and 03(1.05%) respectively. At the same time, the highest number of the patient’s parents were illiterate 166(58.04%), in contrast, 120(41.96%) had completed their education and had knowledge about oral hygiene (Table I).

Discussion:
Fungal organisms are a dire source of nosocomial infections as well as cause significant ailments among children. Modern medicine is faced with great challenges, considering the increased length of hospital stay and high healthcare costs in children and patients with nosocomial infections. A relevant study by Walsh et al. in France found a strong correlation between mortality of acute candidiasis and children. He noted that about 10-15% of oral candida-infected children are suspected of septicemia. The present study was highlighted to evaluate the prevalence of oral candidiasis and to compare the type of causative candida species in children.

In our study female candida infected patient was remarkably high with 169 (59.09%) than male. It was probably for the reluctant attitude to the girls in the low socio-economic condition’s population as in our study the low-income people were significantly high with 217(75.87%). We noted that age ranged from one year to five years was the grave victim of oral candida infection which plummeted with the increase of age. As this early age group population is fully dependent on their parents for maintaining their oral hygiene so it was purely for the lack of proper oral care knowledge and lack of education of their guardians.

In our study, the most commonly detected Candida species were C. Albicans (86.34%), C. tropicalis (8.68%), C. guilliermondii (1.24%), C. glabrata (0.62%), and C. krusei (3.12%). C. Albicans has been found to be the long recognized as well as the most common cause of disseminated candidiasis, followed by C. glabrata Albicans species in both child and adult patients. Another factor of candida infection is the imposition of economic burden on the patient due to the increased costs of care including the investigation fees, the use of antifungal agents and, even more for some time the prolonged length of hospital stay due to the development of fungal pneumonia. The common funga pathogens in the child department. Nowadays a greater emphasis has been given for the reliable, less time-consuming, and cost-effective identification methods for detecting Candida species. It is also important to identify the infecting strains of the
Candida because isolates of Candida species differ extremely, both in their ability to produce infection and also in their susceptibility to antifungal agents. Therefore, efforts should be made to prevent this fungal infection.
