Introduction

Neonatal sepsis is defined as systemic inflammatory response of the body to an infection during first 28 days of life diagnosed either on microbiologic cultures or strong clinical evidence of an infection. Upto 25% of children in intensive care units have sepsis. Worldwide neonatal sepsis is responsible for 4 million deaths annually, most of them occur in developing countries where mortality rate is between 11-68 per 1000 live birth and in Bangladesh rate is 42 per 1000 live birth. Group B streptococcal (GBS) disease is the most important cause of neonatal sepsis in Europe, but there is preponderance of gram negative organism in tropical and developing countries. It has been seen that gram negative organism are leading pathogen in Bangladesh. Apart from mortality, morbidity associated with neonatal sepsis includes sensorineural hearing loss, visual disturbances, seizures, and neurodevelopmental issues. This life-threatening condition is treatable if diagnosed early but unfortunately, the early signs and symptoms are often nonspecific and confusing which makes it difficult to establish an early clinical diagnosis. As a result of this uncertainty antibiotics are often started on the slightest clinical suspicions of sepsis. This approach is effective in fighting against the acute infections, but increases the risks of antibiotics side effects and the emergence of drug resistant organisms in neonatal units. Blood culture is considered as gold standard for diagnosis of sepsis. A drawback of culture based diagnosis is the assay time of up to 36 hours. After 36 hours of incubation period, sensitivity and specificity are 100%. Measures of acute phase proteins,
cytokines, cell surface antigens, and bacterial genomes have been used, either alone or in combination, for early diagnosis of neonatal sepsis. Some of these markers are sensitive and specific, but sophisticated or expensive so impractical for developing countries like ours. Early diagnosis of neonatal sepsis is still a great challenge. Many attempts have been made to develop a set of screening tests for early and rapid diagnosis of the infected neonates.

Therefore the ideal diagnostic test should have quick results, inexpensive and adequate sensitivity, specificity, positive predictive value and negative predictive value to reliably exclude sepsis and avoid unnecessary antibiotic therapy. In this regards early diagnosis of neonatal sepsis a hematological scoring system (HSS) of Rodwell are preferable because it includes all parameters. Hematological scoring system (HSS) that we studied includes complete blood picture and C reactive protein estimation (CRP) which is quick and cost effective.

Patients and Methods

This prospective study was conducted at intensive care unit, department of pediatrics, Dhaka Shishu Hospital during the period of June 2014 to December 2014. All the newborns aged 0 to 28 days presented with maternal history of premature rupture of membranes, intrapartum fever or clinical signs of sepsis namely; neonatal fever or hypothermia, poor feeding and lethargy or depressed neonatal reflexes were included in this study. Neonates who presented with major congenital anomaly, inborn error of metabolism, severely jaundiced due to blood group incompatibilities or RDS due to surfactant deficiency were excluded from this study. After taking a careful history previously designed and developed questionnaire was filled up with detailed information and recorded by the investigator. With all aseptic precaution at least 2 ml of blood was withdrawn from suspected sepsis patients within 24 hours of admission. 1ml sample was anticoagulated with EDTA and using automated hematology analyzer, values of total leucocyte count (TLC), differential leucocyte count and platelet count were noted. Peripheral blood smears were stained by Leishman method. 1ml of blood was inoculated aseptically into conventional blood culture bottle sent to department of microbiology, Dhaka Shishu Hospital for culture and sensitivity. Patient was scored according to hematological scoring system (HSS), incorporating increase or decrease in leukocyte count, absolute neutrophil count, immature PMNs count and platelet count. Degenerative changes in PMNs (toxic granulation and vacuolation) which have seen with Giemsa stained slides. CRP estimation was also performed (Table I). Score of 3 was considered as positive.

CRP= C-reactive protein,
ANC= Absolute neutrophil count (neutrophils % x total WBC count).
PMN =Polymorphonuclear cell

The investigation for sepsis include complete blood counts, ANC, band form, toxic granulation, vacuolation, platelet count, CRP measurements and blood culture. Findings of HSS were recorded in a proforma and later compared with results of blood cultures.

Interpretation of Hematological Scoring System

The study was conducted on 128 neonates presenting with clinical features suspected of neonatal sepsis. Out of 128 neonates, there were 65.6% male neonates and 34.4% female. In this study Nearly half of the newborns (35.1%) were preterm. On presentation HSS was applied on all neonates with suspected neonatal sepsis and the results were obtained that 32% had positive HSS and 68% had negative results. Most of them had raised CRP (32%) and low platelet count (25%) (Table II).
Definitive diagnosis of septicemia is made by positive blood cultures and negative predictive value was 95% (Table III).

Sensitivity = 71%, Specificity = 73%, Positive Predictive Value = 24%, Negative Predictive Value = 95%.

After HSS assessment all neonates were underwent blood cultures and neonatal sepsis was seen in 11% (culture positive) of cases and negative in 89%. On applying the formulae for calculation, sensitivity of HSS was found to be 71% and specificity 73%. The positive predictive value of HSS was 24% and negative predictive value was 95% (Table III).

### Discussion

Despite the advances in neonatal care, early onset neonatal sepsis remains a serious and potentially life-threatening disease. The signs and symptoms of neonatal sepsis may be subtle and nonspecific being clinically indistinguishable from various noninfectious conditions and metabolic disorders. It is the current practice to start empirical antibiotic therapy in all neonates showing infection-like symptoms. However, this may expose newborns to risk of adverse drug effects on one hand and lead to nosocomial complications and the emergence of resistant strains on the other. Accurate and quick diagnosis is therefore essential so that timely treatment of a potentially fatal disease can be provided and at the same time damages deriving from the unnecessary use of antibiotics be prevented. The definitive diagnosis of septicemia is made by a positive blood culture, which requires a minimum of 48-72 hours, yields a positive result in 10-60% of cases. Blood culture remains the gold standard for diagnosis of neonatal sepsis, yet it is important to develop effective screening tools which can presumably diagnose or exclude neonatal sepsis at the time of presentation and that is why this study was carried out. Early diagnosis of neonatal sepsis is still a great challenge. For early diagnosis of neonatal septicemia a hematologic scoring system (HSS) of Rodwell was introduced in the past. It included hematological parameters and showed that such score could accurately predict the presence or absence of infection and be reliable. The HSS assigns a score of 1 for each of seven hematologic findings and shown to be significantly (P<0.005) associated with sepsis. As no single individual haematological parameter is superior in comparison to another in predicting neonatal sepsis, a combination of these parameters in the form of HSS has been recommended. Hematologic scoring system (HSS) should improve the efficiency of the CBC as a screening test for sepsis until a reliable diagnostic test is available. The HSS has practical advantages; it is applicable to all infants, including those who have received antibiotic therapy prior to evaluation and simplifies the interpretation of hematologic profile. In this study with a cut off score 3 we observed a sensitivity of 71%, specificity of 73%, PPV 24%, NPV 95%. These results were consistent with other studies. Many studies performed to evaluate the haematological scoring system for the early diagnosis of neonatal sepsis revealed variable results, but all points towards its utility. Ghosh et al and Narasimha et al reported that Immature PMN count and I:T PMN ratio is sensitive indicator of neonatal sepsis. Degenerative changes in the PMNs made no significant contribution in the diagnosis, in this study. Presence of toxic granules indicates the production of unusual PMNs during infection and stress induced leucopoiesis. They are never seen in healthy babies. Their presence invariably indicates sepsis, but their count is not always increased. Thrombocytopenia was frequently associated with sepsis and indicated poor prognosis. This is thought to be due to increased platelet destruction, sequestration secondary to infections, failure in platelet production due to reduced megakaryocytes or damaging effects of endotoxin. Higher the score on HSS, more are the chances of sepsis. The simplification and standardization of the interpretation of this global test is still required. Variety of other rapid detection methods of microorganisms, like DNA probes, automated blood culture system and fluorometric detection systems are also available globally, but HSS can still be used as a screening test for diagnosing sepsis and to differentiate infected neonates from the non-infected ones. Furthermore, the sensitivity and the specificity of the test are also high, with certainty of sepsis increasing with the score. Murphy et al reported on 100%
sensitivity and 100% negative predictive value of two normal white blood cell counts (WBC) within 8 to 12 hours and a negative blood culture at 24 hours for ruling out early-onset sepsis in the neonate. Measurement of immature neutrophil granulocytes has been considered to be a helpful early indicator of various infectious conditions and has a long clinical tradition in the diagnosis of bacterial sepsis in neonates. CRP is one of the most widely available; most studied, and most used laboratory tests for neonatal bacterial infection. It is well known that it provides limited sensitivity when determined during the early phases of the disease, especially at the initial presentation, but provides very high negative predictive values and is thus useful for identifying infants unlikely to be infected or monitoring the response to treatment. Use of CRP in neonatal sepsis is complicated by a nonspecific rise that starts shortly after birth.

In this study 10.9% neonates were considered as proven sepsis by blood culture. However suspected sepsis groups comprises a difficult diagnostic group and could not be ignored, because fatal infection had been reported in the presence of negative blood culture.

Conclusion
Haematological scoring system is a simple, quick, readily available effective tool with high sensitivity and specificity in the early diagnosis of neonatal sepsis.
