Ventricular septal rupture (VSR) after acute myocardial infarction with the consequence of hemodynamic instability is a rare complication and it's a medical emergency. Mortality of these group patients is higher than 90% to 95% without a rapid diagnosis and correction by surgical intervention. Spontaneous closure of VSR is extremely rare. We report the case of a patient with acute myocardial infarction with ventricular septal rupture (VSR) with cardiogenic shock that was diagnosed in our modern coronary care unit by the bedside portable echocardiographic machine (vivid).

The incidence of ventricular septal rupture (VSR) after acute myocardial infarction is extremely rare in this reperfusion era. This condition is associated with a high mortality rate, even after the cardiac surgery. Our case emphasizes the risk factors and evolution of this condition.

A 36 years old hypertensive young man was admitted on 8th August, 2014 through the emergency department of university cardiac centre for central chest pain, dyspnea, nausea and bilateral shoulder pain for the last 7-8 days. He consulted with his family physician for the same complaints and later he was referred to get admission in our hospital. The patient’s condition was deteriorating gradually. Physical examination revealed a regular pulse of 110 beats/min. The blood pressure was 100/70 mmHg and there was a systolic murmur best heard at the apex, radiating to the axilla. Pulmonary rales were present and there was no peripheral edema, hepatomegaly and raised JVP.

The 12-lead electrocardiogram (Figure 1) showed sinus rhythm at 125 beats/min, low voltage QRS complex voltage in the limb leads, q waves in II, III, AvF and a 4 mm ST elevation in the anterior leads (V2-4).

Serum troponin T level at admission was 1.75 ng/ml, CK-MB 28, Serum creatinine 1.25, Serum electrolytes are within normal limit.

He was managed as a case of acute antero-septal MI with old inferior MI and on the following day after his admission he developed cardiogenic shock. Examination reveals pulse was 115 beats/min and blood pressure was 80/40 mm of Hg. Then we put the patient under inotrope support, transthoracic echocardiography was done and (figure 2, 3 & 4) revealed a small rupture of the apical ventricular septum (figure 2) causing a VSR with left-to-right shunt (figure 3) and Doppler study showed the pressure gradient.

Fig.-1: Electrocardiogram at admission.
The hemodynamic status worsened gradually requiring inotropic support with dopamine and dobutamine along with other anti ischemic therapy. Now the patient is feeling relatively well as there is no chest pain, no nausea, no shoulder pain except generalized weakness. His vitals are as follows. Pulse 105 beats/min, BP 100/80 mm of Hg (with ionotrophic support), respiratory rate 21/min, SPO2 – 97%, bilateral basal crepitations present.

Discussion:
VSR is a rare but serious complication of acute Myocardial infarction that is, in almost all cases, fatal without early surgical intervention. It had an incidence of 1-3% in the era before reperfusion therapy, decreasing with the introduction of thrombolytic therapy.\(^1,2\) VSR is more infrequent than a rupture of the ventricular free wall. Women are affected more commonly than men. Other risk factors are age, non-smoking and hypertension. VSR usually occurs 2-8 days after the infarction and often precipitates cardiogenic shock. There are a few reported cases of silent myocardial infarction followed by an asymptomatic VSR or presenting as chronic congestive heart failure\(^4\). The size of the defect determines the magnitude of the left-to-right shunt and consequently the hemodynamic deterioration, which affects survival. Complete spontaneous closure of such an acquired defect is extremely rare\(^5\). There are three types of VSR (the original classification made by Becker and van Mantgem was for free-wall rupture): in type I there is an abrupt tear in the wall without thinning; in type II, the infarcted myocardium erodes before rupture and is covered by a thrombus; and type III represents the perforation of a previously formed aneurysm.\(^6\) The blood supply to the septum originates from branches of the left anterior descending coronary artery, the posterior descending branch of the right coronary artery, or the circumflex artery when it is dominant. VSR has equal frequency in anterior and non-anterior infarctions.\(^7\) Anterior MI is associated with rupture of the apical septum, in inferior MI, it often occurs at the base of the heart. An MI associated with a VSR is usually extensive. Early treatment of MI with thrombolysis may reduce the incidence of VSR, influence the time to septal rupture and improve the outcome. Development of thrombi in the left ventricle after myocardial infarction is not uncommon. In contrast, right ventricular thrombi are rare. Right heart thrombi may also develop in situ as a result of blood stagnation in patients with a cardiomyopathy or with catheter or pacemaker leads. Floating right heart thrombi in most cases are seen by accident, in transit from deep veins to the pulmonary artery.
If a patent foramen ovale or atrial septal defect is present, a thrombus can cross from the right atrium directly into the left atrium with paradoxical embolism. The direct demonstration of paradoxical embolism by imaging a thrombus traversing the foramen ovale is unusual. Our case illustrates the typical risk factors of VSR: an extensive acute myocardial infarction (anterior, with right bundle branch block) in an old hypertensive, non-smoking woman, with no history of angina. We have described a rare situation in this rare condition—the partial occlusion of the defect by a thrombus—which may have slowed the evolution.
